It may be argued that further work is justified. Cross-sectional studies or further case-control studies would provide a means of studying this problem without the substantial resources needed for a major cohort study. However, it must be remembered that the overall risk of death after anaesthesia and surgery is low.[2] The impact of cardiovascular risk factors is greatest in populations in which the underlying risk is greatest, such as in vascular and other major surgery. It is towards such groups that future investigations should be directed.

Myocardial ischaemia after coronary artery bypass grafting: early *vs* late extubation

P. D. BERRY, S. D. THOMAS, S. P. MAHON, M. JACKSON, M. A. FOX, B. FABRI, W. I. WEIR AND G. N. RUSSELL

Summary

The technique of early extubation after coronary artery bypass grafting is increasing in popularity, but its safety and effect on myocardial ischaemia remain to be established. In a randomized, prospective study, patients undergoing routine elective coronary artery bypass grafting were managed with either early or late tracheal extubation. The incidence and severity of electrocardiographic myocardial ischaemia were compared. Data were analysed from 85 patients (43 early extubation; 42 late extubation). Median time to extubation was 110 min in the early extubation patients and 757 min in the late extubation patients. After correction for randomization bias, there were no significant differences between groups in ischaemic burden, maximal ST-segment deviation, incidence of ischaemia and area under the ST deviation–time curve (integral of ST deviation and time). Similarly, there were no differences between groups in postoperative creatine kinase MB-isoenzyme concentrations and duration of stay in the ICU or hospital. Therefore, this study provides evidence for the safety of early extubation after routine coronary artery bypass grafting. (*Br. J. Anaesth.* 1998; **80**: 20–25)

Keywords: heart, ischaemia; heart, coronary artery bypass grafting; intubation tracheal

Traditionally in the anaesthetic management of coronary artery bypass grafting (CABG) attempts are made to attenuate the stress response to surgery, often using high-dose opioids and late tracheal extubation after a prolonged period of postoperative sedation and ventilation. In practice, use of a low-dose opioid balanced anaesthetic technique allows tracheal extubation to be performed within 1 h of surgery.[1] However, recent studies have revealed a high incidence of postoperative myocardial ischaemia within the first 8 h after CABG, which may be associated with adverse cardiac outcome.[2–4] Postoperative high-dose opioid sedation and other measures designed to attenuate the stress response have been shown to reduce postoperative myocardial ischaemia.[5–6] Although demonstrable cost savings and shortened ICU and hospital stays[7–9] have led to the increasing popularity of early extubation, the safety of performing tracheal extubation during this high-risk period for myocardial ischaemia remains to be established. We have therefore carried out a randomized, prospective study using continuous ECG monitoring to compare the occurrence of myocardial ischaemia between an early extubation, low-dose opioid technique and a late extubation, high-dose opioid technique.

Patients and methods

After obtaining approval from the local Ethics Committee and written informed consent, we studied 98 patients undergoing routine elective CABG. We excluded those patients who were unlikely to be suitable for early extubation or who had ECG abnormalities making the diagnosis of myocardial ischaemia difficult. These included patients aged more than 71 yr, those receiving digoxin, and those with left or right bundle branch block on preoperative ECG (QRS duration $\geq$0.12 s), morbid obesity (body mass index greater than 35), FEV_1 or FVC values less than 50% of predicted or poor left ventricular function (CASS score[10] greater than 15 or ejection fraction <30%). Data collected included: age, sex, history of previous myocardial infarction, hypercholesterolaemia, smoking, hypertension, diabetes mellitus, preoperative use of nitrates, calcium antagonists, beta blockers and CASS score obtained at preoperative cardiac catheterization.

PEROPERATIVE MANAGEMENT

Anti-anginal medication was continued up to and including the morning of surgery. Patients received oral diazepam 0.1 mg kg^{-1} as premedication 2 h before surgery. On arrival in the operating room, patients were allocated to either early extubation (group E) or late extubation (group L), according to a prepared randomization schedule. Group E patients received fentanyl 50 μg kg^{-1}; group L patients received fentanyl 15 μg kg^{-1}. Anaesthesia was induced in both groups using either etomidate or diazepam. Neuromuscular block was produced with vecuronium, and anaesthesia was maintained with isoflurane in 100% oxygen. At the end of surgery,

group E patients were given neostigmine 0.03 mg kg^{-1} and glycopyrrolate 0.06 mg kg^{-1} to antagonize residual neuromuscular block.

Cardiopulmonary bypass was performed using a membrane oxygenator. All operations were performed by one of two surgeons (B. F. and W. I. W.) using either anterograde–retrograde warm blood cardioplegia with systemic normothermia or intermittent cross-clamp/fibrillation with moderate systemic hypothermia (30–32 °C). Surgeons were asked to assess the quality of the grafts and distal run-off as excellent, good, fair or poor, and to assess the overall quality of myocardial revascularization as either satisfactory or unsatisfactory. Total duration of aortic cross-clamping and duration of cardiopulmonary bypass were recorded.

POSTOPERATIVE MANAGEMENT

After transfer to the intensive care unit (ICU), group L patients received i.v. infusion of propofol 50–300 mg h^{-1} without the use of a loading or bolus dose. Sedation with propofol was maintained such that patients were unresponsive to tracheal suction or gentle shaking. If sedation lightened they were given i.v. boluses of morphine 5 mg, and the propofol infusion was increased until sedation reached the required level. After a period of at least 8 h, propofol infusion was discontinued and patients were allowed to awake. Group E patients were allowed to awake immediately after entering the ICU.

Patients in both groups were excluded from the study if they failed to fulfil the following criteria throughout the period of ECG monitoring: haemodynamically stable (not requiring more than 6.5 μg h^{-1} of epinephrine); blood loss less than 120 ml h^{-1} and arterial P_{O_2} $\geqslant$10 kPa with an inspired oxygen concentration of 50%; and PEEP$\leqslant$5 cm H_2O. Tracheal extubation was carried out when the patient was awake and co-operative and could maintain an arterial P_{CO_2} $\leqslant$7 kPa during spontaneous respiration. Patients in group E had a target time to extubation of within 8 h of admission to the ICU. The trachea of patients in group L was extubated more than 8 h after admission to ICU but before the end of the study (24 h after induction of anaesthesia). After extubation, analgesia was provided using i.v. morphine delivered by patient-controlled analgesia devices.

Direct arterial pressure and heart rate were recorded every 5 min in the ICU using Marquette Tramscope 12 monitors archived to a desktop computer.

ELECTROCARDIOGRAPHY

An AM Holter monitor (Series 8500, Marquette Electronics) was attached to the patient at the time of induction of anaesthesia and monitoring was continued for 24 h, except while the patient was on cardiopulmonary bypass. Three ECG leads were recorded (modified CMV4, modified CMV5 and CS-AVF1). Holter tapes were analysed by two investigators blinded to the study group and clinical details, using a Marquette series 8000 automated ECG analysis system and standard techniques. All abnormal QRS complexes including artefact, ventricular ectopics and beats with bundle branch block were excluded. Patients with fewer than 10 h of acceptable beats in the post-bypass period were excluded. Beats classified as normal were subjected to ST-segment analysis. ST-segment deviation from the isoelectric point was trended continuously, both at the J-point and at J + 60 ms. If the J + 60 ms point was on the T-wave, ST deviation was measured at J + 40 ms. Episodes of myocardial ischaemia were defined as: either ST elevation of $\geqslant$2 mm or ST depression of $\geqslant$1 mm, measured as absolute deviation from the isoelectric point. In all analyses ST segment changes had to persist for more than 1 min and had to be reversible for at least 1 min before the end of the recording. For each ischaemic episode a sample of the ECG trace was printed as hard copy and reviewed by two investigators (S. T., P. B.) to exclude artefact. In each patient who had one or more ischaemic episodes the following were calculated: ischaemic burden (total duration in all three leads of ischaemia divided by number of hours monitored); area under the ST-deviation–time curve (AUC), which was also corrected for the number of hours monitored; and average maximal ST-segment deviation during the ischaemic episode. For each ischaemic episode, systolic arterial pressure and heart rate at the time of onset were compared with the median values for the preceding 25 min. A change of $\geqslant$20% was regarded as indicating an episode of ischaemia which was related to haemodynamic alteration. The incidence and characteristics of ischaemia occurring in the pre-bypass period (between induction of anaesthesia and onset of cardiopulmonary bypass) were also recorded.

CARDIAC OUTCOME MEASUREMENTS

The following were recorded for each patient: duration of stay in hospital; concentrations of MB isoenzyme of creatine kinase (CK-MB) on the first 3 days after operation; and daily 12-lead ECG for the first 3 days after operation. Non-fatal myocardial infarction was defined as a concentration of CK-MB greater than 130 iu $litre^{-1}$ and development of a new Q-wave ($\geqslant$40 ms and $\geqslant$0.4 mV) or new left bundle branch block on the postoperative 12-lead ECG. The incidences of in-hospital death, use of intra-aortic balloon pump and ventricular arrhythmias requiring treatment were also recorded.

STATISTICAL METHODS

During the design of the study, a 1-mm difference in maximal ST-segment deviation between the early and late extubated groups was felt to represent clinically important effects of different extubation policy. As such this study was designed to be 80% confident that should such differences be observed, they were attributable to extubation policy and not chance. Estimates based on the variability seen in previous studies[5] indicated that approximately 40 patients in each limb of the study were necessary to achieve this power.

Categorical data are presented as counts and continuous data as median (5th and 95th centiles). All continuous data received a test of normality. The integrity of the randomization was checked by exploring the possibility that differences between patient characteristics, preoperative and operative variables stratified by early or late extubation were attributable to something other than chance using a chi-square or Fisher's exact test for categorical data or a Wilcoxon rank sum test for continuous data. Differences in postoperative ischaemia and other outcome measures were similarly explored. $P \leq 0.05$ was considered significant for these univariate analyses.

Results

Of the 98 patients admitted to the study, ECG analysis was completed in 85 patients. Reasons for exclusion of the remaining 13 patients are given in table 1. These 13 patients were excluded from further data analysis.

PREOPERATIVE AND SURGICAL DATA

Although patients were allocated randomly to study groups, analysis of preoperative data (table 2) revealed higher prevalences of essential hypertension ($P = 0.038$) and beta-blocker therapy ($P = 0.030$) in the early group. This prompted the use of multivariate analysis of covariance to assess the true effects of extubation policy on postoperative ischaemia, independent of these confounding factors.

There were no other differences between groups in patient and clinical preoperative data, surgical assessment of graft quality or quality of revascularization (table 3).

TRACHEAL EXTUBATION

Median times to tracheal extubation were 110 (range 4–255) min in group E and 757 (499–1240) min in group L. Of the 13 patients who failed to complete the study (table 1), four patients were excluded because of extubation problems: in three patients in group E the trachea could not be extubated within the designated period of 8 h because of inadequate Pa_{CO_2} or Pa_{O_2} values during spontaneous breathing and one patient in group E had inadequate arterial $P\mathrm{o}_2$ in the period before extubation.

USE OF GLYCERYL TRINITRATE AND EPINEPHRINE

More group E patients (77%) than group L patients (48%) received glyceryl trinitrate in the ICU (P = 0.006); 14% of group E patients *vs* 31% of group L patients received epinephrine in the ICU (P = 0.06).

PRE-BYPASS ISCHAEMIA

Nine patients in group E and 10 in group L had pre-bypass ischaemia. There were no significant differences between groups in the prevalence, duration, AUC or maximal ST-segment deviation of ischaemia in the pre-bypass period (table 4).

POST-BYPASS ST CHANGES

Median duration of monitoring in the postoperative period was 19 (range 14–21) h for group E and 19 (11–21) h for group L

ST depression and ST elevation

Twenty-two of 43 (51%) group E patients and 17 of 42 (40%) group L patients had episodes of ST depression or ST elevation, or both (P = 0.323) in the post-bypass period (fig. 1). When other ST characteristics (AUC, ischaemic burden and maximal ST deviation) were examined, analysing only those patients with ST changes, there were no significant differences between groups (table 5, fig. 2).

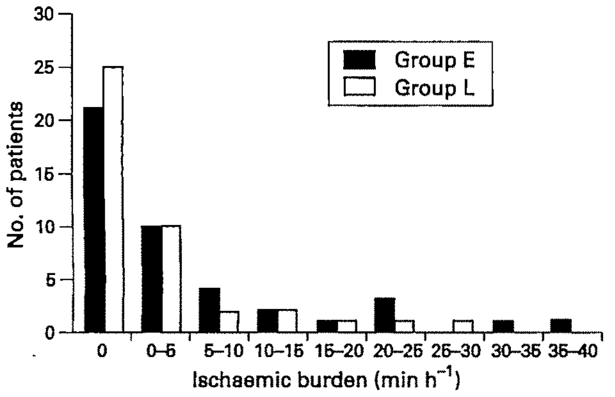

Figure 1 Distribution of ischaemic burden in patients in groups E and L with ischaemia characterized by ST elevation or ST depression.

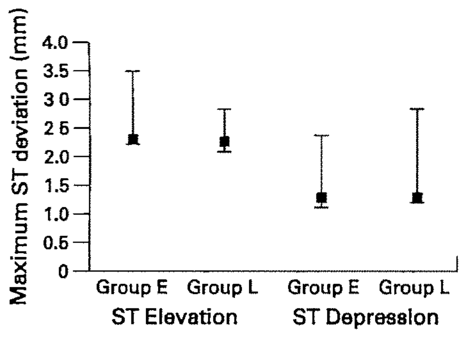

Figure 2 Maximum ST-segment deviation during ischaemic episodes in patients in groups E and L (median (5th–95th centiles)).

ST depression alone

Twenty of 43 (47%) patients in group E compared with 11 of 42 (26%) in group L had episodes characterized by ST depression (P = 0.029, chi-square test).

Analysis of patients with ST depression revealed no differences in other characteristics of ischaemia between early and late extubation patients (table 6). However, when all patients (i.e. those with or without ST changes) were included in analysis of characteristics of ischaemia, there was a greater ischaemic burden and AUC in the early extubation group (mean ischaemic burden in group E = 4.06 mm h^{-1} *vs* group L = 1.98 mm h^{-1}, P = 0.044; mean AUC in group E = 5.28 mm min *vs* group L = 2.75 mm min, P = 0.044). MANOVA analysis was used to correct for the influence of the excess of patients with essential hypertension and preoperative beta-blocker therapy in the early group. This resulted in no significant differences between groups (P = 0.440 for AUC, P = 0.383 for ischaemic burden).

In general, ST segment changes were not related to alterations in heart rate or arterial pressure (six of 204 ischaemic episodes in group E; 10 of 155 episodes in group L were related to haemodynamic changes). Similarly, ST changes did not appear to be related to tracheal extubation: only 15 of 204 ischaemic episodes in group E and four of 155 episodes in group L occurred within 30 min before or after extubation.

OUTCOME MEASUREMENTS

Two patients (group L) died during their hospital stay, both during the postoperative ECG monitoring period while in the ICU, both with acute cardiac failure. Two patients in group E and two in group L developed non-fatal MI (new significant Q-waves or new left bundle branch block, and CK-MB values greater than 130 iu litre^{-1} in any of the first 3 days after operation). Of the four patients who developed non-fatal MI, three had ischaemia in the postoperative period. None of the four patients had pre-bypass ischaemia. Plasma CK-MB values were similar in both groups on postoperative days 1 and 2. No patients developed sustained ventricular arrhythmias, required an intra-aortic balloon pump or died in hospital after discharge from the ICU to the general wards. Time spent in the ICU and duration of hospital stay were similar in the two groups (table 7).

Discussion

We have measured the duration and severity of pre- and postoperative ischaemia by recording ST-segment depression and elevation. The only significant difference in outcome between the late and early groups was a greater prevalence of ST depression ischaemia in the early group. The validity of this finding must be interpreted in light of a pre-existing potential bias after randomization of patients: an excess of hypertensive patients in the early group. No reason other than chance could be invoked to explain the occurrence of such a randomization bias. Essential hypertension in patients with good left ventricular function is often treated by beta-adrenergic block, the significant difference between the two groups in

ICU stay (days)	2 (2–2)	2 (2–4)	0.55

the use of these drugs is therefore not surprising. When MANOVA was used to correct for this bias, differences in ischaemia between groups disappeared. This raises the possibility that the greater prevalence of ST depression ischaemia was a result solely of the greater prevalence of essential hypertension in group E. This is supported by previous findings of characteristically abnormal diastolic ventricular function in hypertensive patients with abnormal coronary blood flow leading to a greater risk of compromised perfusion and myocardial ischaemia.[11–14]

The use of continuous ECG monitoring to detect myocardial ischaemia is well established. Nevertheless, there is no universally accepted "gold standard" for the detection of myocardial ischaemia in the postoperative situation and it is now appreciated that caution is also necessary in the ECG diagnosis of ischaemia because of the high incidence of ECG abnormalities after CABG compared with non-cardiac surgery.[15] Criteria for interpretation of post-CABG ECG ischaemia are still evolving. In our study we used criteria comparable with those of the SPI group[2 3 5] to define ischaemic episodes. Our separate analysis of ST-segment depression episodes in addition to analysis of combined ST depression and ST elevation allows more direct comparison with other studies which have used ST depression alone as a marker of ischaemia,[16 17] and with studies which have examined both ST elevation and ST depression but found significant results with ST depression alone.[5]

A variety of ECG leads have been used in previous studies. Two of the three leads used in our study (modified CM-V4, CM-V5) should have detected at least 90% of ischaemia compared with full 12-lead electrocardiography,[18] and the use of the third lead CS-AVF1 detects ischaemia occurring in the distribution of the left and right circumflex and left anterior descending coronary arteries,[19 20] and increases sensitivity of ischaemia detection to 96%.[21]

More patients in group E compared with group L received glyceryl trinitrate (GTN) to treat emergence hypertension after operation. More group L patients received epinephrine after operation although this was not significant. These findings were probably a result of the well recognized hypotensive effect of deep sedation and propofol,[22] despite avoidance of an initial loading or bolus dose. A confounding effect of GTN is unlikely, as GTN has been shown to have no effect on myocardial ischaemia during CABG.[23]

In six (12%) of a total of 50 patients originally allocated randomly to group E, the trachea could not be successfully extubated early. This incidence is comparable with previous studies.[24 25] With current anaesthetic and surgical techniques, it seems likely that an irreducible small proportion of patients fail early extubation. This however does not negate the overall validity or usefulness of the technique.

Previous studies have examined post-CABG myocardial ischaemia, and have reported incidences of myocardial ischaemia ranging from 3%[26] to 48%.[3] This wide range reflects differing methods and criteria for diagnosing myocardial ischaemia, in addition to different therapies and patient populations. Nevertheless, the overall incidence of ischaemia in our patients was comparable with that of other studies. Our finding that ischaemic episodes were not related to haemodynamic instability[3 5 20 21] or to tracheal extubation[27] is similar to the findings of other studies.

The SPI group compared deep sufentanil–midazolam sedation with morphine–midazolam for patients who underwent ventilation after CABG and found that the sufentanil group had less severe ST-segment depression than the morphine group.[5] This study was one of the first to raise the issue of post-CABG ischaemia. In both groups in this study the trachea was extubated late. Their sufentanil group received considerably more opioid than the morphine group, and the greater severity of ischaemia in the morphine group may reflect relatively poor analgesia and sedation in patients receiving artificial ventilation via a tracheal tube. In our study, patients were either kept deeply sedated or the trachea was extubated and patients given adequate analgesia with patient-controlled morphine administration. This may account for the similarity between our two study groups.

One other study has directly compared ischaemia in early and late extubation after CABG.[25] In this study, anaesthetic and postoperative management were broadly similar to the present study, although sedation was with midazolam in late extubation patients and propofol in early extubation patients. Although a trend is apparent, with early extubation patients having a higher incidence of ischaemia in 10 of 12 four-hourly periods in which postoperative ischaemia was recorded, a statistically significant difference in ECG ischaemia could not be demonstrated between study groups, which is consistent with our own findings.

The importance of the stress response in post-CABG ischaemia remains unclear, and the optimum timing and approach to attenuating it are similarly not known.[28] For this reason we have not measured any biochemical indicators of the stress response. However, even allowing for an important role for the stress response in postoperative ischaemia, it appears that plasma catecholamine and steroid concentrations are similar with early or late extubation,[25 29] which is consistent with our finding of no difference in ischaemia between early and late extubation groups. The clinical relevance of this and similar studies rests on the assumption that postoperative myocardial ischaemia is a potential predictor of adverse cardiac outcome, and on the ECG diagnosis of myocardial ischaemia in the post-CABG patient. Although some workers have failed to find such a correlation[5 30 31] raising the possibility that perioperative ischaemia after CABG is in fact a benign epiphenomenon, others have suggested a relationship between postoperative myocardial ischaemia after CABG and adverse cardiac events.[2 3 32] Our study, with a low incidence of adverse cardiac outcome (MI or cardiac death) had insufficient power to add to this particular debate.

In conclusion, when corrected for randomization bias, we found no difference in the prevalence of postoperative myocardial ischaemia in patients whose trachea was extubated within 8 h of surgery compared with those in which extubation occurred later. Early extubation appears to be a safe option, although in our practice we have failed to demonstrate any benefit in terms of duration of ICU or hospital stay.

Mast cell tryptase in anaesthetic anaphylactoid reactions

M. M. FISHER AND B. A. BALDO

Summary

Increased concentrations of mast cell tryptase are a highly sensitive indicator of anaphylactic reactions during anaesthesia. We obtained serum specimens from 350 patients after possible anaphylactic reactions during anaesthesia. Serum was collected from patients in our own institution (27), and transported by mail and courier from other hospitals in response to a request in the medical literature (323). Concentrations of mast cell tryptase were measured in 416 specimens. Intradermal testing was performed in 217 patients and radioimmunoassay for drug-specific antibodies with serum in 198 patients. Mast cell tryptase concentrations were increased in 158 patients, equivocal in 10 and not increased in 182. There was a significant difference in the incidence of positive intradermal tests, radioimmunoassay tests and evidence of an IgE-mediated reaction in patients whose mast cell tryptase concentrations were increased. Seven of 143 patients whose mast cell tryptase concentrations were not increased at appropriate sampling times had positive tests for IgE antibodies, and in 33 of 158 patients with increased mast cell tryptase concentrations no IgE antibodies were detected. We conclude that increased mast cell tryptase concentrations are a valuable indicator of an anaphylactic reaction during anaesthesia. Their presence favours an IgE-mediated cause but does not always distinguish between anaphylactoid and anaphylactoid reactions, and patients in whom mast cell tryptase concentrations are not increased still require skin testing. (*Br. J. Anaesth.* 1998; **80**: 26–29)

Keywords: allergy; complications, anaphylaxis; enzymes, tryptase.

Mast cell tryptase (MCT) is an enzyme released from activated mast cells but not basophils[1] and is detectable in serum 1–6 h after anaphylactic reactions.[2 3] It can be used to diagnose anaphylaxis in post-mortem specimens.[4–6] We report the results of MCT measurements in 350 consecutive patients and their correlation with other allergy tests.

Patients and methods

The availability of the assay was notified and specimens were requested in the Australian anaesthetic literature. Anaesthetists were asked to collect three serum specimens between 1 and 8 h after a suspected anaphylactic reaction during anaesthesia. Specimens were transported frozen. In 26 patients with fatal reactions, serum was obtained at post mortem in 14, ante mortem in nine and at both times in three. After data from the first 40 patients were analysed, the timing was altered to a single test between 1 and 6 h after the start of the reaction. Multiple specimens were still assayed if sent.

Control blood specimens were obtained from patients 1 h after cardiopulmonary bypass,[2] haemorrhagic shock[2] and septic shock.[2]

MCT was assayed using a commercial radioimmunoassay (Pharmacia).

MCT was described as increased if concentrations greater than 3 μg litre^{-1} were detected in ante-mortem specimens, and concentrations greater than 5 μg litre^{-1} in postmortem specimens (2448); concentrations less than 2 μg litre^{-1} were regarded as not increased. Intermediate concentrations were described as equivocal.

MCT concentrations that were not increased were considered to have been obtained at appropriate times if ante-mortem sampling occurred between 1 and 6 h after the reaction, and for postmortem specimens, if the patient died between 1 and 6 h after the start of the reaction and the post mortem was performed within 3 days of death.[4–6] All specimens with increased values were deemed to have been obtained at appropriate times, even if no times were recorded.

Intradermal testing was performed with drugs diluted to concentrations determined unlikely to produce reactions as a result of direct histamine release according to methods described previously.[7–9] Radioimmunoassay (RIA) test for specific drugs used methods described previously.[10–16]

Results

Concentrations of MCT were increased in 158 patients, equivocal in 10 patients and not increased in 182 patients (table 1). In those patients whose MCT concentrations were not increased, the sampling time was inappropriate in 21 and not stated in 18. Fourteen of these patients had evidence of IgE antibodies by intradermal testing,[5] RIA,[5] or both.[3] None of the controls had increased MCT concentrations.

Table 1 Mast cell trytase concentrations, and results of radioimmunoassay (RIA) and intradermal (ID) testing in 350 patients with adverse reactions during anaesthesia

Group	No. of patients	ID positive/ performed	RIA positive/ performed	IgE detected
MCT not increased	182	11/98	9/96	14/154
No time given	18	0/2	0/7	0/8
Time inappropriate	21	5/9	5/15	7/9
Appropriate sample	143	6/87	4/81	7/137
MCT equivocal	10	0/6	0/2	0/6
MCT increased	158	108/113	72/101	125/158

Table 2 Significance of IgE involvement and positive intradermal tests (ID) and drug-specific radioimmunoassay tests (RIA) in patients with increased and normal mast cell tryptase concentrations performed at an appropriate time (chi-square test)

Group	No. of patients	ID positive/ performed	RIA positive/ performed	IgE detected
MCT not increased	143	6/87	4/81	7/137
MCT increased	158	108/113	72/101	125/130
Chi-square		154.1	78.6	217.6
P		<0 00001	<0.00001	<0.00001

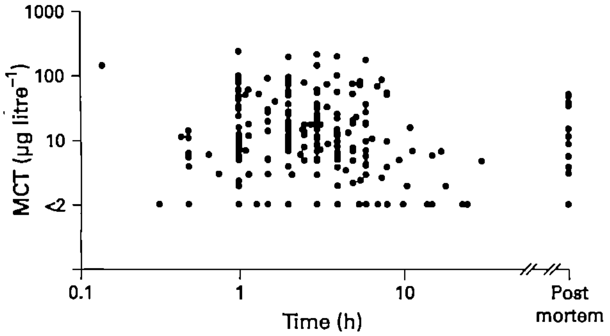

Figure 1 Concentrations of mast cell tryptase (MCT) in patients reacting with suspected anaphylaxis during anaesthesia: 253 measurements in 172 patients with at least one increased value or evidence of immune-mediated reactions, or both.

The results of intradermal and RIA testing in patients with and without increased MCT concentrations are shown in table 2. There was a significant relationship between increased MCT concentrations and positive intradermal tests (chi-square = 74, df = 1, $P = 0.0001$) and between increased MCT concentration and RIA tests (chi-square = 27, df = 1, $P < 0.0001$). On the basis that these tests suggest IgE-mediated reactions, there was a significant association between increased MCT concentrations and immunological IgE-mediated reactions. However, seven patients with evidence of IgE antibodies to a drug and a good clinical history did not show increased MCT concentrations at an appropriate sampling time and in 158 patients with increased MCT concentrations no evidence of IgE antibodies was obtained by intradermal testing in five, RIA in three and both in three. Another 28 patients did not have the appropriate investigations performed to detect IgE antibodies, as intradermal testing was not performed and a valid RIA did not exist.

Figure 1 shows MCT concentrations in patients with at least one increased value or evidence of IgE involvement, or both. The earliest recording of an increased MCT value was at 15 min and the latest at 23 h. However, three patients with increased MCT concentrations between 1 and 6 h showed no increase in specimens obtained before 30 min or after 4 h.

Table 3 shows the drugs responsible for the reactions.

Twenty-six patients died: in 15 the history suggested anaphylaxis, and MCT concentrations were increased in 11, with inappropriate sampling times in three others. In one patient, MCT was increased but the sample was collected in a fluoride tube and control bloods in fluoride tubes showed increased MCT concentrations. In two patients, high concentrations of MCT led to an unsuspected diagnosis of anaphylaxis. In one of these, a coroner's inquest had determined cardiac disease as the cause of death. In nine patients, two ante-mortem and seven postmortem specimens showed no increase in MCT concentrations and RIA tests were negative in seven. None had a history suggestive of anaphylaxis. The RIA test was positive in eight of the 13 patients with increased MCT concentrations and negative in three. In four patients who had post-mortem and ante-mortem specimens, both assays were increased. MCT concentrations in patients who died were significantly higher than the maximum concentrations in patients with IgE-mediated reactions who survived (56.3 (55.5) *vs* 28 (26.8) μg litre^{-1}; $P < 0.05$, Student's *t* test).

Discussion

The classical symptoms of anaphylaxis are more commonly produced in anaesthesia by mechanisms other than true anaphylaxis. Further, the direct histamine releasing effects of anaesthetic drugs may mimic anaphylaxis, and unlike anaphylaxis the clinical features may not recur if the drug is administered more slowly. Thus a test which accurately answered the question "Is this an anaphylactic reaction?" would be of great value. Furthermore, such a test may determine who needed to be investigated by skin or RIA testing subsequently and would be a valuable tool for selecting a homogeneous population to evaluate tests for drug allergy. At present the difficulty in determining who is allergic clinically makes negative tests more difficult to interpret.

Although drug-specific IgE concentrations at the time of reaction may determine the nature of the reaction,[17] such tests are not available for all drugs and are more reliable when positive, with up to 40% false negative results for some drugs.[9] Plasma histamine concentrations may demonstrate an anaphylactoid reaction but these tests are difficult and samples need to be obtained within 10 min of the reaction occurring, a time when resuscitation is a priority. Early studies by Laroche and colleagues[17 18] suggested that demonstration of increased MCT concentrations was associated with immunological reactions, and this was supported by our earlier studies.[5 9]

The results of this study showed that increased MCT concentrations were associated usually with immunological reactions. Unfortunately, this was not invariably so. Four patients who had proven anaphylaxis with a strong history and positive tests (positive RIA tests in two) did not show increases in MCT. It is unlikely that the RIA and intradermal tests were false positives. Laroche and colleagues[18] described a mechanism that may account for this discrepancy involving reactions caused by immunological release of anaphylactic mediators from basophils (which do not release tryptase[1]) and not mast cells. In their series, 50% of such patients had positive skin tests. The potential serious consequences of misdiagnosing anaesthetic anaphylaxis suggests that patients without increased MCT concentrations should be investigated if severe anaphylaxis is likely from the history.

In 33 patients with increased MCT concentrations we found no evidence of an immunological reaction. In 28 of these, intradermal tests were not performed and RIA tests were not available for the likely agent. Five patients had negative intradermal tests and four of these had negative RIA tests. One patient in whom the history was conclusive for allergy to a Gortex vascular graft required high-dose steroids to suppress anaphylaxis and had no histamine responsiveness at the time of testing, but four others had a strong history of anaphylaxis and the intradermal and RIA tests were probably false negatives. It may be that these patients do not have antibodies on skin mast cells. These patients are to be investigated further to endeavour to find the agent responsible.

Although the statistical data showed that increased MCT concentrations were associated with immunological reactions, increased MCT concentrations may occur with direct histamine release. Direct histamine release from mast cells *in vitro* is associated with increased MCT concentrations,[19] and patients with mastocytosis have increased concentrations.[20] A patient in the non-anaesthetic part of this study had repeated uneventful exposures to vancomycin by infusion and died from a bolus dose of vancomycin, with the highest concentrations we have recorded (238 u. litre^{-1}). In this context, reactions to Haemaccel are interesting. Our studies confirmed those of Vervloet and colleagues[21] that 50% of these patients have positive skin tests and yet we have repeatedly been unable to demonstrate anti-gelatin antibodies in patients who react to Haemaccel. The assumption that positive skin tests indicate IgE-mediated reactions may not be valid for Haemaccel, and the tests may demonstrate exaggerated histamine release from skin mast cells.

The cost of performing an MCT test is approximately $A14 per patient. This cost would be justifiable when the tests are negative if the need for intradermal testing (cost $A22–120)[22] is avoided. This also may remove the cost of travel (which often involves long distances in Australia) to the patient. Detection of seven patients with IgE antibodies and no increase in MCT concentrations suggests that patients without increased MCT concentrations still require skin testing.

There were practical difficulties in providing this testing as a laboratory service to anaesthetists: 20% of the request forms did not have the time of sampling which led to the necessity of attempting to acquire this information as it was feared that sending a report of a negative MCT when sampling has occurred at the wrong time may lead to the assumption that anaphylaxis did not occur with adverse consequences for the patient and medico-legal implications for the anaesthetist and laboratory. The tests were performed in batches of 40 tests and five controls, 45 times per year. This has two implications: first, if the result is awaited before follow-up testing, the optimum time for skin testing may be exceeded; second, the results were usually obtained after discharge and filed in the patient's records without being seen by an anaesthetist. Efforts to send a copy of the results to the anaesthetist have been very difficult on many occasions because the test had been ordered by a member of the junior staff.

The data in this study also showed that the suggested time of sampling of 1–6 h[5] should be reduced to 1–4 h as three patients had increased concentrations of MCT within this time but concentrations outside this time were not increased.

The use of the test in fatal reactions confirmed earlier observations[4–6] of unexplained death not caused by anaesthesia, that MCT concentrations obtained in patients who survive between 1 and 4 h after an anaphylactic or unexplained reaction which is fatal may give the diagnosis, with obvious medico-legal implications.

The major causes of the reactions were neuromuscular blocking drugs, antibiotics and Haemaccel, which differ from our previous studies[9] but are in keeping with Australian studies of critical incidents.[23] We believe that this difference is related largely to the emergence of the cephalosporins as a significant cause of anaphylaxis during surgery in the past few years and to the fact that reactions to Haemaccel were not investigated in our previous studies. Of interest is the number of reactions to antibiotics in which MCT concentrations were not increased: Kuenneke and colleagues[24] suggested that non-histamine related cardiovascular abnormalities may be associated with antibiotic administration in 25% of major surgery.

Succinylcholine is now the most common cause of anaesthetic anaphylaxis in Australia as it is in the rest of the world, replacing alcuronium. This is probably related to usage.[9]

The higher number of patients in whom a diagnosis was reached in the group with increased MCT concentrations was related to the higher specificity of the tests in this group but was biased by the more thorough pursuit of results of intradermal testing after an increased MCT was found.

We conclude that MCT is a useful measurement after a possible anaphylactic reaction during anaesthesia. Sampling should occur between 1 and 4 h after a reaction, and the time of sampling and the reaction should be clearly indicated to the laboratory. Increased MCT concentrations are highly suggestive of an immune cause but may reflect direct histamine release. Patients with increased concentrations of MCT must be investigated for an allergic cause and patients without increased MCT concentrations should be investigated if the clinical picture suggests severe anaphylaxis.

Effect of positive end-expiratory pressure on the incidence of venous air embolism and on the cardiovascular response to the sitting position during neurosurgery

R. Giebler, B. Kollenberg, G. Pohlen and J. Peters

Summary

We have studied prospectively the effect of 10 cm H_2O of PEEP on the incidence of venous air embolism and on the cardiovascular response to change from the supine to the seated position in a large neurosurgical population. Patients were allocated randomly to receive either PEEP (10 cm H_2O, $n = 45$) or conventional (control, $n = 44$) ventilation. Cardiovascular and respiratory variables were measured in the supine and sitting positions, and monitoring included precordial Doppler probe, pulmonary artery pressure and expiratory carbon dioxide concentration. Venous air embolism was assumed if changes in precordial Doppler sounds occurred, end-tidal carbon dioxide concentration decreased or air could be retrieved from a central venous multi-orifice catheter. The incidence of venous air embolism (26%) did not differ between patients undergoing conventional ventilation and those undergoing ventilation with 10 cm H_2O of PEEP. Venous air embolism was always detected first by alterations in Doppler sounds. Cardiac output was significantly higher in patients undergoing conventional ventilation than in those undergoing ventilation with PEEP in the supine but not in the sitting position. Furthermore, pulmonary vascular resistance increased significantly only in the upright position in those undergoing ventilation with PEEP. The pulmonary artery wedge pressure to central venous pressure gradient did not attain negative values with PEEP or with upright positioning. We conclude that the use of PEEP during neurosurgical procedures performed in the sitting position should be abandoned as it does not decrease the incidence of venous air embolism but is associated with significant adverse cardiovascular effects. Keywords: embolism, air; position, effects; ventilation, positive end-expiratory pressure; ventilation, mechanical; surgery, neurological

Venous air embolism (VAE) may occur whenever venous pressure at the site of surgery is below atmospheric pressure and it may have devastating effects in patients undergoing neurosurgical procedures in the sitting position. The reported incidence of VAE varies widely, depending on the methods used for its detection, and incidences from 15% to 35% have been reported.[1-3] Positive end-expiratory pressure (PEEP) has been recommended for many years for the prevention and mitigation of the effects of further VAE,[4 5] despite the experimental observation that PEEP may fail to increase intracranial venous pressure.[5] However, PEEP may decrease mean arterial pressure[6] and reverse the left-to-right inter-atrial pressure gradient which might predispose patients with a probe-patent foramen ovale to the risk of paradoxical air embolism.[7] Accordingly, some authors do not advocate routine use of PEEP during craniotomy in the sitting position.[8] Nevertheless, 78% of all hospitals described the use of PEEP in a questionnaire on perioperative management during operations performed in the sitting position.[9]

However, because either only few patients were examined in prospective studies[8 10 11] or data were collected retrospectively,[2 3] differences in patient management and study design may not allow evaluation of the risk:benefit ratio of PEEP during neurosurgical procedures in the sitting position. Therefore, we studied prospectively in a large number of patients the effect of PEEP on the incidence of VAE in seated neurosurgical patients. Haemodynamic variables during ventilation with PEEP in both the supine and sitting positions were also examined, hypothesizing that PEEP (1) decreases the incidence of VAE, and (2) alters the pressure gradient between pulmonary capillary wedge and central venous pressures.

Patients and methods

After obtaining local Ethics Committee approval and written informed consent, we studied prospectively 89 consecutive adult patients (31 men, 57 women; mean age 52.3 (range 18–75) yr) undergoing elective neurosurgical procedures in the sitting position (85 suboccipital craniotomies, four cervical laminectomies) during a 1-yr period. Patients were allocated randomly to either PEEP (10 cm H_2O, $n = 45$) ventilation or conventional ventilation (control, $n = 44$). There were no exclusion criteria.

All patients were given flunitrazepam 1 mg orally, 1 h before operation. Anaesthesia was induced with propofol 1.5 mg kg^{-1} i.v., alfentanil 50 μg kg^{-1} i.v. and atracurium 0.5 mg kg^{-1} i.v. After tracheal intubation, the lungs were ventilated mechanically with an oxygen–air mixture ($F_{I_{O_2}}$ = 0.5) either conventionally with a PEEP of 3 cm H_2O (control) or a PEEP of 10 cm H_2O. End-tidal carbon dioxide partial pressure was adjusted to 4.0–4.3 kPa. Anaesthesia was maintained by continuous infusion of propofol 5 mg kg^{-1} h^{-1}, alfentanil 125 μg kg^{-1} h^{-1} and atracurium 0.3 mg kg^{-1} h^{-1}. Before application of the skull clamp and before skin incision, a bolus dose of alfentanil 50 μg kg^{-1} was given. Patients in both groups received Ringer's solution 4 ml kg^{-1} h^{-1} and hydroxyethyl starch solution (10% HES 500 ml) during induction. To record arterial pressure, a 20-gauge polyethylene catheter (Viggo-Spectramed, Montigny le Bretonneaux, France) was inserted into the left radial artery. For measurement of pulmonary arterial, central venous and pulmonary capillary wedge pressures, a four-lumen balloon-tipped pulmonary artery catheter (Thermodilution Catheter 7.5 F, Viggo-Spectramed, Montigny le Bretonneux, France) was inserted via the right internal jugular vein. In addition, a multi-orifice (2 side orifices; Arrow, Central Venous Catheterization Set with Blue Flex Tip; Reading, PA, USA) single-lumen central venous catheter allowing air retrieval in case of VAE was inserted via the right internal jugular vein and positioned near the sinus node using an ECG recorded via the catheter.[12] Vascular pressures, ECG and respiratory carbon dioxide partial pressure were displayed on a monitor and recorded continuously on a strip chart recorder.

With the patient in the seated position a precordial ultrasonic Doppler probe (Dual Frequency Doppler, Model 915-AL, Parks Medical Electronics Inc., Aloha, OR, USA) was placed along the right parasternal border. Proper Doppler placement with detection of intravascular air was verified by rapid injection of 5 ml of agitated saline.[13]

After operation, all patients were transferred to the intensive care unit and the lungs ventilated mechanically.

MEASUREMENTS

Heart rate was recorded from the ECG and cardiac output was assessed by thermodilution (Sirecust 961, Siemens, Erlangen, Germany); the average of three measurements was obtained using 10 ml of iced saline. Systemic and pulmonary vascular resistances were calculated from standard formulae. Arterial, pulmonary artery, central venous and pulmonary capillary wedge pressures in addition to airway pressure (air filled system) were measured by electromanometry relative to barometric pressure. Pressures were referenced to the mid-axillary line in the supine position and to the anterior fifth intercostal space in the seated position. All pressure measurements were recorded continuously on a multi-channel strip-chart recorder (Siredoc 220, Siemens, Erlangen, Germany) at a paper speed of 200 mm min^{-1}.

Respiratory variables (respiratory carbon dioxide partial pressure) were measured proximal to the tracheal tube by in-line infrared radiation absorption (Sirecust 961, Siemens, Erlangen, Germany), and tidal volume and ventilatory frequency by a hot wire anemometer (Anemone, Dräger, Lübeck, Germany). Arterial oxygen saturation was measured by pulse oximetry (PM 8050, Dräger, Lübeck, Germany).

For measurement of blood-gas tensions and pH, and concentrations of electrolytes and haemoglobin, arterial blood was obtained from the radial artery and pulmonary artery and analysed with electrodes at 37 °C (Ciba Corning 288 Blood Gas System, Ciba Corning, Fernwald, Germany).

EXPERIMENTAL DESIGN

Patients were allocated randomly to either ventilation with PEEP or conventional ventilation. Cardiovascular and respiratory variables were measured 15 min after induction of anaesthesia in the supine position (baseline) and 15 min after patients had been positioned in the sitting position. There was no surgical stimulation during these measurements. In patients with VAE, simultaneous measurements of central venous and pulmonary artery pressures were obtained and compared with values of these variables during the 15-min period immediately before air embolism in each patient.

During operation, the presence of VAE was assumed if either (1) changes in precordial Doppler sounds occurred,[11] (2) end-tidal carbon dioxide partial pressure decreased suddenly by more than 0.3 kPa in a step manner[14] or (3) air could be retrieved via the central venous catheter. Furthermore, during VAE, changes in mean arterial, pulmonary arterial and central venous pressures, and changes in arterial oxygen saturation (detected by pulse oximetry) were recorded.

STATISTICAL ANALYSIS

Results are reported as mean (SEM) unless otherwise indicated. Haemodynamic data were analysed by two-way analysis of variance for repeated measurements followed by *post hoc* Newman–Keuls test. A chi-square test was used to compare incidences of events between groups during different study conditions. The following *a priori* null hypotheses were tested: ventilation with PEEP (1) does not change the incidence of VAE and (2) does not alter values of cardiovascular variables. Results were considered to be statistically significant with an α error of $P < 0.05$.

Results

INCIDENCE OF VENOUS AIR EMBOLISM

VAE was detected by a Doppler signal suggestive of air entry in 23 patients (26%), 11 undergoing PEEP ventilation and 12 undergoing conventional ventilation. The incidence of VAE did not differ significantly ($P = 0.95$) between patients undergoing PEEP ventilation (24%) and those undergoing conventional ventilation (27%). Aspiration of air in those patients showing signs of air embolism was possible (recovered air volume 4–25 ml) in six patients (55%) in the PEEP group and in five (42%) in the conventional ventilation group. There was no significant

difference in the amount of air aspirated or the incidence of successful air aspiration between groups.

INCIDENCE AND SEVERITY OF HAEMODYNAMIC ALTERATIONS AND CHANGES IN END-EXPIRATORY CARBON DIOXIDE TENSION WITH VENOUS AIR EMBOLISM

Approximately 60% of all detected venous air entries were followed by haemodynamic alterations. Most frequently, an increase in pulmonary artery pressure ($n = 13$; 57%) was observed (PEEP group, six (55%) patients; control group, seven (58%) patients), whereas a decrease in mean arterial pressure (PEEP group, two (18%) patients; control group, three (25%) patients) or an increase in central venous pressure (PEEP group, two (18%) patients; control group, two (17%) patients) was seen less often.

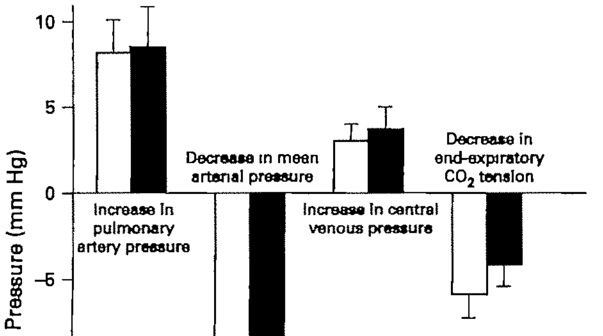

Figure 2 Cardiovascular alterations and changes in end-expiratory carbon dioxide tension associated with venous air embolism in neurosurgical patients undergoing ventilation with 10 cm H_2O of PEEP and in patients undergoing conventional ventilation.

VAE was accompanied by a similar incidence of a decrease in end-expiratory carbon dioxide tension (in seven (64%) patients in the PEEP group and in 10 (83%) patients in the control group). In fact, the mode of ventilation did not alter the sensitivity of different monitoring modalities to detect VAE with alterations in Doppler sounds considered the gold standard (fig.1).

Neither the significant increase in pulmonary artery pressure (PEEP +8.5 (2.4) mm Hg; control +8.2 (1.9) mm Hg) nor the significant decrease in mean arterial pressure (PEEP −14.1 (1.9) mm Hg; control −15.3 (2.1) mm Hg), central venous pressure (PEEP +3.5 (1.4) mm Hg; control +3.0 (0.9) mm Hg) or carbon dioxide tension (PEEP −0.6 (0.2) kPa; control −0.8 (0.2) kPa) associated with air embolism were significantly affected by the amount of end-expiratory airway pressure. Therefore, there was no significant difference in the incidence or severity of cardiorespiratory alterations after VAE between patients in the PEEP and those in the conventional ventilation group (fig. 2).

EFFECT OF PEEP AND POSITIONING ON CARDIOVASCULAR VARIABLES

Moderately but significantly higher pulmonary artery pressure and pulmonary capillary wedge pressure values were observed in the PEEP group compared with the conventional ventilation group both in the recumbent and in the seated position. Central venous pressures was greater with PEEP in the sitting position but not in the supine position. Of note, pulmonary artery wedge pressure was higher than central venous pressures in the supine position in all patients.

When patients were placed in the seated position, pulmonary artery pressure, pulmonary capillary wedge pressure and central venous pressure decreased significantly (table 1). As pulmonary

capillary wedge pressure remained higher than central venous pressure in all patients, the pulmonary artery wedge pressure to central venous pressure gradient did not attain negative values and did not change significantly with positioning in patients undergoing ventilation with PEEP (P = 0.116) and in those undergoing conventional ventilation (P = 0.233). Figure 3 depicts the pulmonary capillary wedge pressure to central venous pressure pressure gradients of all patients in the PEEP and conventional groups, both in the supine and sitting positions.

As expected, cardiac index was significantly lower in supine patients undergoing ventilation with PEEP compared with those undergoing conventional ventilation; in seated patients, cardiac index decreased markedly in both groups. However, with patients in the sitting position significant differences in cardiac index were no longer observed between groups (table 1).

There was no significant difference between groups in pulmonary vascular resistance while in the supine position. Furthermore, pulmonary vascular resistance increased significantly with PEEP only in the upright position (table 1). Although mean arterial pressure tended to decrease and systemic vascular resistance to increase after attaining the seated position, these differences were not significant with regard to mode of ventilation or body position (table 1).

Discussion

This study was the first to assess prospectively and in a randomized manner the impact of PEEP on the incidence of VAE and on cardiovascular alterations in a large number of patients operated on in the sitting position. We found that ventilation with a PEEP of 10 cm H_2O during neurosurgical procedures in the seated position offered no benefit but rather may be harmful.

Because reliable measurements and interpretation of results depend on central venous and pulmonary artery wedge pressures measured accurately in the supine and seated positions, we referenced all pressures to the mid-axillary line in the supine position and to the anterior fifth intercostal space when patients were in the seated position.[10] [11] There is consensus that pulmonary artery wedge pressure reasonably reflects mean left atrial pressure in the absence of cardiac valve abnormalities and during some unphysiological states (i.e. PEEP values up to 10 cm H_2O or more[15–17]). As the pressure gradient between central venous pressure and pulmonary capillary wedge pressure is normally small, minor differences in the technique of measurement could alter the results obtained. Thus all variables were recorded continuously with each transducer referenced to zero repeatedly and compared between groups at similar times. Another possible source of error is that the pulmonary artery catheter tip might be wedged in regions where pulmonary capillary wedge pressure reflects airway pressure rather than left atrial pressure. However, Benumof and colleagues found important peripheral catheter locations in only 6.9% of patients in whom a pulmonary artery catheter had been inserted.[18] Therefore, from a statistical point of

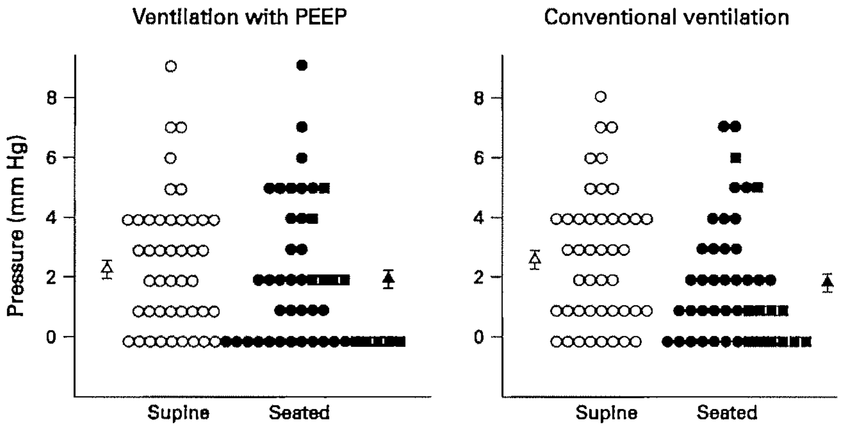

Figure 3 Pulmonary capillary wedge pressure to central venous pressure gradient in 45 patients undergoing ventilation with 10 cm H_2O of PEEP (left) and in 44 undergoing conventional ventilation (right) in the supine and sitting positions. Individual and mean (SEM) values are given. Square symbols indicate patients suffering from venous air embolism.

view, false measurements caused by catheter misplacement are unlikely to have influenced the results in our 89 patients. Furthermore, to avoid possible changes in pulmonary catheter position (e.g. by use of PEEP itself), we ventilated the lungs of our patients with either PEEP or conventionally without changing airway pressure within a study group. Thus pressures measured and comparison between groups should have yielded reliable data.

The overall incidence of VAE (26%) observed in this study is consistent with that reported in several other series.[2 3 11] With no difference in the incidence of VAE with and without PEEP, however, our data do not confirm the results of Lee, Lichtman and Weintraub[19] who reported a decrease in VAE from 55% in patients whose lungs were ventilated without PEEP (n = 9) to 26% in patients who underwent ventilation with 10 cm H_2O of PEEP (n = 19). However, as a PEEP value of up to 15 cm H_2O has no detectable effect on sagittal[20] or transverse[21] sinus pressure in humans, our results demonstrating PEEP to be ineffective in preventing VAE were not unexpected.

We used a precordial Doppler probe to detect VAE. With 0.25 ml of air injected i.v. already altering Doppler sounds,[22] precordial Doppler monitoring is more sensitive in detecting VAE than measurements of end-expiratory carbon dioxide partial pressure or pulmonary artery pressure.[14] However, these latter two methods have the advantage of providing quantitative physiological information on the sequelae of venous air emboli and return of pulmonary artery pressure towards baseline can serve as a guide for the effectiveness of therapy.[23] Our data are in accordance with these reports as changes in Doppler sounds always preceded a decrease in end-expiratory carbon dioxide tension and cardiovascular changes in both the conventional ventilation and PEEP groups. In addition, we could not demonstrate a significant impact of PEEP on the cardiovascular responses associated with VAE.

Historically, the incidence of VAE was associated with procedures on the head, neck, chest and in the post-partum period. Recently, VAE has been detected, for example in orthopaedic hip replacement and abdominal procedures, in addition to neurosurgical procedures in the prone, lateral or supine position.[24] Therefore, VAE is not restricted to the sitting position and it may be speculated if our findings can be applied to these situations.

Pulmonary artery pressure, pulmonary artery wedge pressure and central venous pressure were higher during PEEP ventilation. This is not surprising as PEEP exerts its major cardiovascular effects by increasing intrathoracic pressure.[25] When patients were moved from the supine to the sitting position, vascular pressures decreased regardless of whether or not PEEP was applied, mirroring the decrease in venous blood return to the heart and diminished filling of the pulmonary circulation. These data are consistent with previous results[26 27] demonstrating in spontaneously breathing supine humans assuming the sitting position that intrathoracic blood volume decreased by approximately 300–500 ml with a decrease in both pulmonary artery wedge and central venous pressures. Techniques which are used to maintain filling pressures in the sitting position such as anti-gravity suits or high volume management were not used in this study. However, filling pressures measured in our patients did not differ from those reported in studies using anti-gravity suits.[28 29] As the increase in filling pressures induced by anti-gravity suits has been reported to be only transient in adults[28 30] we rarely use anti-gravity suits in our department. Whether PEEP may be effective in decreasing the incidence of VAE in patients with filling pressures higher than reported so far is beyond the scope of this investigation.

Depletion of the central circulation was also the likely reason for the decrease in cardiac output observed in both groups after patients were seated. However, in the seated position cardiac output in patients who underwent conventional ventilation was not significantly different compared with that during ventilation with PEEP. Presumably, this reflects the pronounced effect of positioning compared with PEEP ventilation or, conversely, the small additional circulatory depressant effect of PEEP in the seated position. Possibly, a much greater increase in PEEP may change this pattern but this has not been evaluated.

While PEEP increased both pulmonary artery wedge pressure and central venous pressure, it failed to affect the pulmonary capillary wedge pressure: central venous pressure gradient. In contrast, Perkins and Bedford reported that 10 cm H_2O of PEEP caused reversal of this pressure gradient in the seated position.[8] However, their results were from only 11 patients, with seven (64%) apparently showing a higher central venous than pulmonary artery wedge pressure during application of PEEP. In contrast, Zasslow and colleagues[10] observed a higher central venous than pulmonary artery wedge pressure in only one of 12 patients whose lungs were ventilated with 20 cm H_2O of PEEP in the seated position. Therefore, with only 11, 12 or six patients per study group, the results of these studies are inconsistent[10 11 31] and may have led to misrepresentation of the risk of developing a negative pulmonary capillary wedge pressure:central venous pressure gradient.

Pulmonary vascular resistance increased significantly only in seated patients in the PEEP group but was not affected by PEEP application in the supine position or by positioning in those ventilated conventionally. Similar to the unchanged pulmonary vascular resistance observed in our conventional ventilation group when seated, pulmonary vascular resistance did not increase significantly in anaesthetized humans whose lungs were ventilated without PEEP when placed in the upright position.[10 27] Most likely, pulmonary vascular resistance increased in our seated patients who underwent ventilation with 10 cm H_2O of PEEP because of the additional impairment of pulmonary vascular filling by positioning, possibly causing smaller pulmonary vascular dimensions and hence increased flow resistance.[32]

The data of this prospective, randomized study in a large number of patients demonstrated that ventilation with 10 cm H_2O of PEEP failed to decrease the incidence of VAE and did not alter the sensitivity of monitoring devices to detect VAE. Furthermore, both PEEP and seated positioning impaired cardiovascular performance, with a small cardiac output measured in seated patients whose lungs were ventilated with PEEP. However, positioning *per se* appears to have had a much greater effect on cardiac output and pulmonary vascular resistance than PEEP. We suggest therefore that routine use of 10 cm H_2O of PEEP during neurosurgery in the seated position has no apparent benefit and cannot be recommended.

Role of thromboxane and leukotriene B_4 in patients with acute respiratory distress syndrome after oesophagectomy

M. K. SCHILLING, N. GASSMANN, G. H. SIGURDSSON, B. REGLI, C. STOUPIS, M. FURRER, C. SIGNER, C. REDAELLI AND M. W. BÜCHLER

Summary

We have studied prospectively the clinical course and serum concentrations of thromboxane B_2 (TxB_2) and leukotriene B_4 (LTB_4) in patients developing adult respiratory distress syndrome (ARDS) after oesophagectomy. The clinical course was assessed according to a validated ARDS score, and intra- and postoperative measurements of TxB_2 and LTB_4 in pre- and post-pulmonary blood were performed in 18 patients undergoing oesophagectomy for oesophageal carcinoma and 11 control patients undergoing thoracotomy and pulmonary resection. Six of 18 patients undergoing oesophagectomy, but no control patient, developed ARDS. The ARDS score was highest on day 8 after operation. Only patients with ARDS had a significant postoperative increase in post-pulmonary, but not pre-pulmonary, TxB_2 concentrations ($P < 0.05$ *vs* patients without ARDS). This study provides evidence that TxA_2, originating from the lungs, was associated with the development of ARDS after oesophageal resection. In view of the high incidence of ARDS after oesophagectomy (10–30%), prophylactic treatment of patients undergoing oesophageal resection with clinically applicable thromboxane synthetase inhibitors may be warranted. (*Br. J. Anaesth.* 1998; **80**: 36–40)

Keywords: lung, adult respiratory distress syndrome; complications, adult respiratory distress syndrome; surgery, gastrointestinal; hormones, thromboxane; hormones, leukotrienes

Adult respiratory distress syndrome (ARDS) is one of the primary contributors to mortality in ICU patients.[1] A wide variety of clinical conditions such as sepsis, burns, trauma[2-4] and major surgery, and oesophageal resections in particular,[5 6] predispose to the development of ARDS. In a meta-analysis of more than 60 000 patients undergoing oesophagectomy, 27% developed ARDS after transthoracic resection and 13% after transhiatal resection.[7] The following factors appear to increase the risk of postoperative ARDS in patients with oesophageal carcinoma: smoking and chronic obstructive pulmonary disease (COPD), transthoracic mobilization of the oesophagus with contusion of the lung during extensive surgery and postoperative (silent) aspiration.[8]

Because of the heterogenity of sepsis or trauma patients, it is difficult to acquire comparable study populations for clinical studies of ARDS. In these patients, the triggering insult for ARDS is seldom predictable and it varies greatly in intensity; also, patient conditions such as age, immune and nutritional status and coexisting medical conditions vary widely. Patients undergoing oesophageal resection for oesophageal carcinoma, however, are a homogenous group, with 1–3 of 10 patients developing ARDS.[7] They are usually aged 50–70 yr, the majority have a history of smoking and preoperative weight loss, they are suffering from the same underlying disease, and the duration and magnitude of the insult triggering ARDS (i.e. oesophageal resection) is uniform. In addition, these patients are unique in that they are exposed to a planned triggering factor (i.e. oesophageal resection) which makes post-oesophagectomy ARDS ideal for prophylactic intervention.

In this study we describe the time course of post-oesophagectomy ARDS as being clinically uniform, with a peak of pulmonary infiltrates on day 7 after operation and a typical distribution pattern of pulmonary infiltrates over the four quadrants. We also measured mediators likely to be involved in post-oesophagectomy lung injury: thromboxane B_2 (TxB_2) and leukotriene B_4 (LTB_4) in arterial and central venous blood of patients undergoing oesophageal resection. Patients undergoing thoracotomy and pulmonary resection served as controls. TxB_2 and LTB_4 were chosen because both mediators have been found to induce acute lung injury in animals and both are increased in patients at risk of developing post-traumatic or septic ARDS.[9 10] In addition, inhibitors of TxA_2 and LTB_4 synthesis are available for clinical use,[1 11 12] and these would allow prophylactic treatment of patients undergoing oesophagectomy.

Correspondence to M. W. B.

Committee and informed consent, we studied prospectively 18 consecutive patients undergoing oesophagectomy for oesophageal malignancies and 11 patients undergoing lung resections for pulmonary malignancies (six pneumonectomy, five lobectomy). All patients had combined extradural and general anaesthesia. An extradural catheter was inserted at the T5–7 interspace in all patients before induction of general anaesthesia. An extradural solution containing bupivacaine 1 mg ml^{-1}, fentanyl 2 μg ml^{-1} and epinephrine 2 μg ml^{-1} was infused at a rate of 5–10 ml h^{-1} during operation and maintained for 3–5 days after operation at a rate of 5–15 ml h^{-1}. General anaesthesia was induced according to the departmental routine with thiopental 4 mg kg^{-1}, fentanyl 4 μg kg^{-1} and pancuronium 0.1 mg kg^{-1}, and maintained with 0.3–1.0% isoflurane and 0–70% nitrous oxide in oxygen (according to arterial blood oxygen saturation (Sp_{O_2}>90%)), and repeated intermittent bolus doses of fentanyl and pancuronium as needed. Arterial pressure was monitored continuously via a radial arterial cannula and maintained at a mean arterial pressure of 60–90 mm Hg by adjusting the depth of anaesthesia and infusing blood products, colloids and crystalloids as required. Rarely were catecholamines necessary. The lungs were ventilated to a Pa_{CO_2} of 4.8–5.3 kPa via a left-sided double-lumen tracheal tube, the position of which was controlled by fibreoptic bronchoscopy before surgery started. Arterial oxygen saturation was measured continuously by pulse oximetry and intermittently by arterial blood-gas analysis.

Patients with oesophageal carcinoma were stratified for a one-stage transhiatal or right-sided thoracoabdominal oesophageal resection, according to tumour localization and tumour stage. In all patients undergoing oesophageal resection, the oesophagus was substituted by a gastric tube as described previously.[13 14] A nasogastric tube was placed in the gastric tube for at least 5 days in an attempt to reduce the risk of silent aspiration.[8] After operation all patients undergoing oesophagectomy were kept sedated with morphine 1–7 mg h^{-1} and midazolam 1–5 mg h^{-1}, and their lungs ventilated mechanically via a single-lumen tracheal tube for 48 h and the trachea extubated thereafter, unless they developed pulmonary failure. In the additional 11 patients undergoing right-sided thoracotomy and lung resection (six pneumonectomy and five lobectomy) as a result of bronchial carcinoma, the trachea was extubated at the end of surgery.

All 29 patients were monitored prospectively for development of ARDS. The definition of ARDS used in this study followed the guidelines of the American European Consensus Conference on ARDS: acute onset of bilateral infiltrates seen on chest radiographs with the lowest $Pa_{CO_2}/FI_{O_2} \leq 26.7$ kPa.[15] ARDS severity was assessed using the lung injury score as described by Murray and colleagues[16] (table 1). Lung compliance, positive end-expiratory pressure (PEEP) and Pa_{CO_2}/FI_{O_2} ratio were calculated daily; plain a–p chest x-rays were obtained daily during the early phase of ARDS and every other day in the later course of the illness. Chest x-rays were evaluated by two independent investigators for diffuse infiltrates over the upper and lower pulmonary quadrants.

Table 1 Lung injury score according to Murray and colleagues[16]

	Score
1 X-ray score

4. Total thoracic compliance	
≥80 ml cm H_2O^{-1}	0
60–79 ml cm H_2O^{-1}	1
40–59 ml cm H_2O^{-1}	2
20–39 ml cm H_2O^{-1}	3
≤19 ml cm H_2O^{-1}	4
No lung injury	0
Mild-to-moderate lung injury	0 1–2 5
Severe lung injury	>2.5

Blood samples were obtained simultaneously from a central venous catheter placed in the right atrium and from a radial arterial cannula before surgery, before thoracotomy or during transhiatal dissection of the oesophagus, after closure of the thoracotomy, at the end of surgery and daily after operation between 08:00 and 09:00. Blood was withdrawn into EDTA tubes with indomethacin (to inhibit further leukotriene formation) and centrifuged immediately at 4 °C. Serum was frozen at −80 °C until further processing. At corresponding times, central venous and arterial blood samples were obtained also from patients undergoing lung resection.

ANALYSIS OF EICOSANOIDS

After a SEP-PAK C18-column (Waters, Zürich, Switzerland) extraction from serum, TxB_2, the stable metabolite of the active compound TxA_2, and LTB_4 were measured by commercially available ELISA (Cascade Biochemicals, Reading, UK), as described previously.[17] Intra-assay variabilities for TxB_2 and LTB_4 were 7.8% and 8.4%, respectively; inter-assay variabilities were 8.6% and 6.5%. Normal values in our laboratory for TxB_2 and LTB_4 in venous blood are 115 ± 49 and 89 ± 41 pg ml^{-1} (n = 6). Cross-reactivity for major metabolites for the TxB_2 assay was <1% for PGD_2, 11-dehydro-TxB_2, $PGF_{2\alpha}$ and PGE_2. For the LTB_4 assay, cross-reactivity was 58.8% for LTB_5, 6% for 5(S)-12(S) DIHETE, 4% for 6-trans-LTB_4 and <1% for 5(S)HETE, LTC_4, LTD_4 LTE_4 and prostaglandin metabolites.

STATISTICAL ANALYSIS

Results are presented as mean (SD) for serum concentrations of eicosanoids, mean (95% confidence interval) for the ARDS score and as Σ (sum) of the x-ray score calculated from the six ARDS patients. Regression curves and confidence intervals were calculated using a SigmaPlot software for Windows on a personal microcomputer. Two-tailed Student's t test

and ANOVA with Bonferroni correction were used to calculate differences between groups. Outcome differences were compared by Fisher's exact test.

Results

None of the patients who underwent pneumonectomy (mean age 68.6 (range 52–76) yr, five males, one female) or lobectomy (mean age 64.5 (range 56–69) yr, five males) developed ARDS. Six of the 18 patients who underwent oesophagectomy developed ARDS during the first 3–5 days after operation, requiring prolonged intensive care therapy, including mechanical ventilation (mean 14.4 (7.2) days). In the other 12 patients the trachea was extubated after 48 h and the patient usually discharged to the ward or to a high dependency unit on the same day. Preoperative weight loss in the ARDS patients was significantly greater than in patients who did not develop ARDS (P < 0.05). All other characteristics and preoperative risk factors were comparable (table 2).

The ARDS score over time in the six ARDS patients is shown in figure 1 (regression with 95% confidence interval (CI)). The highest ARDS score (mean 1.75, 95% CI 1.59–1.91, indicating moderate lung injury)[16] was recorded on day 8 after operation. Pulmonary infiltrates were most prominent in the left lower quadrant (maximum x-ray score of 5 on day 7), followed by the right lower quadrant (maximum x-ray score of 4 on day 8), the right upper quadrant (maximum x-ray score of 3 on day 8) and the left upper quadrant (maximum x-ray score of 1 on day 6) (fig. 2). There was no difference in central venous (i.e. pre-pulmonary) TxB$_2$ concentrations between patients who subsequently developed ARDS and patients who did not develop ARDS. Patients undergoing lobectomy but not pneumonectomy showed a slight (P = 0.09) increase in central venous TxB$_2$ concentrations after closure of the thoracotomy. Only patients developing ARDS had a significant increase in arterial (i.e. post-pulmonary) TxB$_2$ concentrations compared with patients who did not develop ARDS (fig. 3). There was no significant difference in venous or arterial LTB$_4$ concentrations between the different groups, but arterial concentrations tended to be higher than venous concentrations (fig. 4).

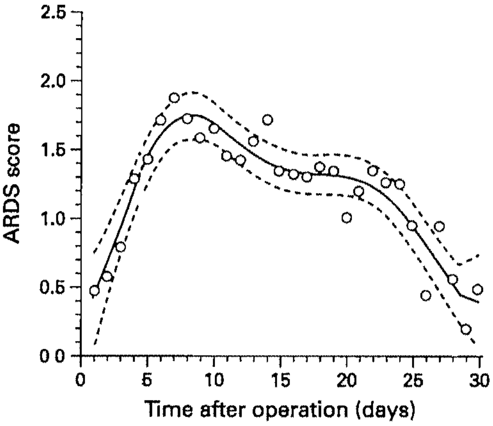

Figure 1 Daily ARDS score for six patients who developed ARDS after oesophageal resection (calculated according to Murray and colleagues[16]). The different points represent the average ARDS score on the given day. Broken lines = 95% confidence interval around the regression curve.

Discussion

The adult respiratory distress syndrome is a severe complication with considerable morbidity and mortality. It occurs frequently after oesophageal resection[7] and requires prolonged intensive care treatment in patients with nutritional and respiratory compromise. Modern multimodal treatment strategies for oesophageal carcinoma, which include preoperative radio-chemotherapy, significantly increase long-term survival of oesophageal cancer patients.[18] The additional radio-chemical damage to the lungs, however, increases the mortality of post-oesophagectomy ARDS further, to almost 50%.[18]

Many attempts have been made to improve the outcome after ARDS by administering various inhibitors of mediators of inflammation to patients at

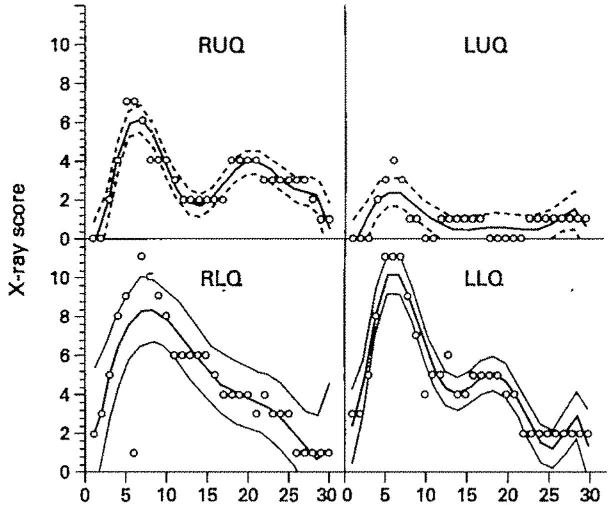

Figure 2 Summarized x-ray scores for six patients who developed ARDS after oesophageal resection (calculated according to Murray and colleagues[16]). The different points represent the summarized x-ray score on the given days. Broken lines = 95% confidence interval around the regression curve. RUQ = Right upper quadrant, RLQ = right lower quadrant, LUQ = left upper quadrant, LLQ = left lower quadrant.

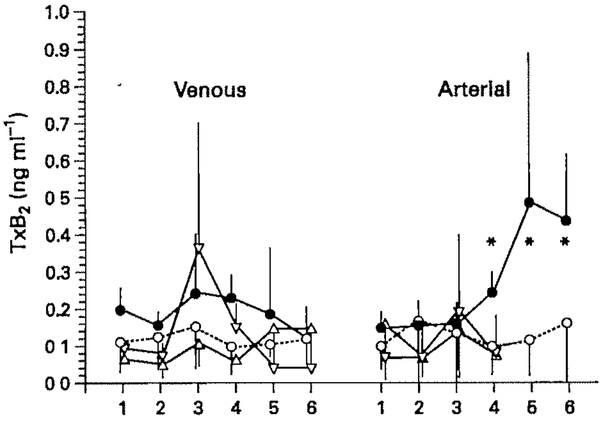

Figure 3 Concentrations of thromboxane B$_2$ (TxB$_2$) in patients who developed ARDS after oesophageal resection (n = 6, filled circles), without clinical signs of ARDS (n = 12, open circles), and in patients who underwent pneumonectomy (n = 6, open triangles) or lobectomy (n = 5, open inverted triangles). 1 = Before operation, 2 = before thoracotomy or transhiatal oesophageal mobilization, 3 = closure of thoracotomy or end of transhiatal oesophageal mobilization, 4 = end of surgery, 5 = postoperative day 1, 6 = postoperative day 2. $*P < 0.05$ compared with patients undergoing oesophagectomy not developing ARDS.

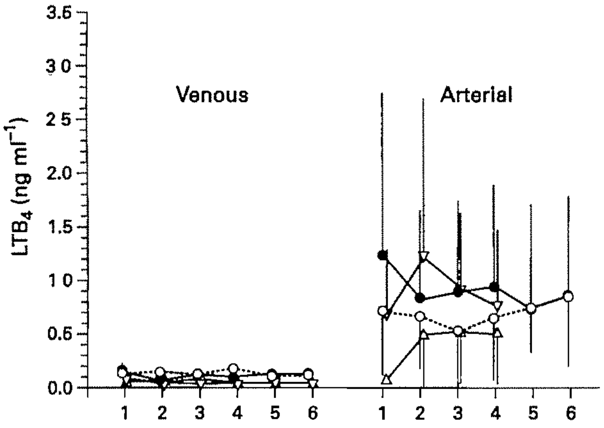

Figure 4 Concentrations of leukotriene B$_4$ (LTB$_4$) in patients after oesophageal resection who developed ARDS (n = 6, filled circles), without clinical signs of ARDS (n = 12, open circles), and in patients who underwent pneumonectomy (n = 6, open triangles) or lobectomy (n = 5, open inverted triangles). 1 = Before operation, 2 = before thoracotomy or transhiatal oesophageal mobilization, 3 = closure of thoracotomy or end of transhiatal oesophageal mobilization, 4 = end of surgery, 5 = postoperative day 1, 6 = postoperative day 2.

risk; however, only few randomized, double-blind, clinical studies have demonstrated improved patient survival.[1] When ketoconazole, a thromboxane A$_2$ synthetase inhibitor, was given to patients at risk of developing ARDS, on admission to the ICU, it appeared to lower the incidence of ARDS and reduce the mortality rate.[1] Experimental studies, however, repeatedly demonstrated beneficial effects of various inhibitors on the incidence or survival of ARDS. In these experiments, healthy animals were exposed to standardized insults and therapy was usually started before or shortly after the insult, which is rarely possible in clinical situations. The main reason for the lack of success in preventing ARDS in high-risk patients therefore appears to be the late start of therapy at a time when cellular responses to the humoral mediators have already been triggered. Patients undergoing oesophagectomy for oesophageal cancer are unusual in this respect and somehow resemble experimental conditions. They are a uniform group and develop ARDS predictably in 10–30% of cases.[7] Furthermore, the triggering insult is an elective surgical procedure which offers the opportunity to treat patients prophylactically, that is before any cascade systems of ARDS have been activated.

Several products of arachidonic acid metabolism are known to be involved in the development of ARDS, both in humans and animals. In this study we measured two metabolites of this cascade, TxB$_2$ (the stable metabolite of TxA$_2$) and LTB$_4$. Both have been shown to be increased in ARDS.[9] [20] Inhibitors of both mediators are available and one has been found to significantly decrease the incidence and mortality of ARDS, both in animals and humans.[1] [11] [12] In patients developing ARDS after oesophagectomy, we found increased concentrations of TxB$_2$, but not LTB$_4$, at the end of surgery, before the clinical appearance of ARDS. Interestingly, TxB$_2$ was increased only in post-pulmonary, but not in pre-pulmonary blood indicating that the lung was the source of thromboxane. Zheng and colleagues suggested that neutrophils, possibly activated by endotoxin,[21] might be the source of thromboxane in ARDS patients. Thromboxane is known to stimulate CD18 facilitated adhesion of neutrophils to pulmonary endothelial cells much more than to other endothelial cells.[22] This may lead subsequently to leucocyte margination, sequestration, adhesion, capillary leakage and pulmonary oedema. Furthermore, thromboxane is a potent vasoconstrictor and procoagulant.[9] It significantly increases pulmonary arterial pressure and causes formation of pulmonary microthrombi, which are known to occur in association with ARDS.[23] [24] In addition, pulmonary endothelial cells have been identified as a rich source of pro-inflammatory eicosanoids.[19]

Patients subjected to pulmonary resection had no increase in thromboxane concentrations despite undergoing thoracotomy and one-lung ventilation in a manner similar to patients admitted for oesophageal resection. This indicates a causative effect unique to oesophagectomy. In an experimental study, Ohwada and colleagues were able to prevent the development of post-oesophagectomy ARDS by preserving vagal nerve branches to the lung,[25] and pulmonary hypertension and bronchoconstriction induced by mediators of ARDS were reversible by stimulation of vagal nerves.[26] While contusion of the lung during pulmonary resection might well cause injury, preservation of vagal branches during lobectomy could prevent the increase in extravascular water associated with the clinical picture of ARDS. In contrast, resections of oesophageal malignancies require high cervical vagal nerve resection for oncological reasons.

Increased serum concentrations of endotoxin in patients undergoing oesophagectomy might be another explanation for the development of post-oesophagectomy ARDS. Endotoxin has been shown to be increased in patients with oesophageal carcinoma before and during surgery,[27] but no such findings have been reported for patients undergoing pulmonary resection for lung cancer. Acute lung injury in patients undergoing oesophagectomy might be a response to a second hit phenomenon, that is increased serum concentrations of endotoxin in the presence of surgical lung trauma.

Leukotrienes, potent chemoattractants and coactivators of neutrophils[22] are increased in bronchial fluid and serum of patients with ARDS, but appear to have no predictive value for the development of ARDS.[10] Our study appeared to confirm this finding as no significant changes in serum LTB_4 were found in any patient during the intraoperative and early postoperative course.

In summary, the association of increased thromboxane A_2 concentrations and the development of ARDS does not exclude other possible causes of ARDS but is consistent with the hypothesis that thromboxane A_2 may have an important role not only in sepsis and trauma, but also in patients developing ARDS after oesophageal resection. The early increase of thromboxane during surgery in arterial blood, but not in central venous blood, suggests that thromboxane originates from the lungs and its synthesis is probably initiated by surgical trauma. The unusual opportunity that oesophagectomy offers for preventive therapy of ARDS should encourage investigators to perform clinical studies in patients undergoing oesophageal resection caused by oesophageal carcinoma using some of the clinically available inhibitors of thromboxane synthesis.

Endogenous source of bacteria in tracheal tube and proximal ventilator breathing system in intensive care patients

T. J. J. Inglis, E.-W. Lim, G. S. H. Lee, K.-F. Cheong and K.-S. Ng

Summary

Although bacteria from both the ventilator breathing system and the gastrointestinal tract have been implicated in the pathogenesis of ventilator-associated pneumonia, an endogenous source of bacteria in the proximal respiratory breathing system has yet to be demonstrated conclusively. We investigated a potential route of bacterial colonization from the stomach contents to the efferent limb of the ventilator breathing system by bacterial culture of daily specimens from six sites in 20 surgical intensive care patients. Gram-negative bacilli were isolated in a progressively increasing proportion of samples at successive sampling points, consistent with an endogenous-to-external route of spread (patients, chi-square = 14.12, $P < 0.02$; samples, chi-square = 106.15, $P < 0.001$). Identical strains of gram-negative bacilli, confirmed by REPS typing, were found at two or more sites in seven patients. In all seven, gram-negative bacilli were first isolated from a site in the patient. In none of the 20 patients was there evidence of a sequence of colonization from the ventilator tubing or Y-piece connector towards the patient. Probable colonization sequences plotted from the time of first isolation supported the proposed sequence in six patients, and in five began with the stomach contents. Isolation sequences contrary to the proposed direction of colonization involved four bacterial species and two patients, and did not extend beyond two sample sites. These findings imply that the retrograde route of bacterial colonization of the ventilated lung extends into the proximal respiratory breathing system and may help to identify additional targets for preventive intervention. Despite a substantial body of evidence implicating bacteria in the gastrointestinal tract as the cause of ventilator-associated pneumonia,[1–9] the role of bacteria in the stomach contents remains controversial.[10] The route followed by these bacteria during their initial entry into and colonization of the lower respiratory tract is an important consideration in preventive strategies designed to prevent ventilator-associated pneumonia.[11–13] Any new insight into this series of bacteriological events would thus be expected to have major implications for the preventive management of the critically ill.

We proposed previously that bacteria from the biofilm on the luminal surface of the tracheal tube might be disseminated into the lungs during the inspiratory phase of mechanical ventilation.[14] Further studies on the static and dynamic properties of tracheal tube biofilm in tubes from intensive care patients support the occurrence of fluid dynamic events in the tracheal tube and other parts of the proximal respiratory breathing system,[15 16] but bacteria in the luminal biofilm and their subsequent dissemination within the proximal breathing system have yet to be linked to a gastrointestinal source.

In this study, we have examined a possible retrograde route of bacterial transfer from the stomach via the tracheal tube to the efferent tubing in intensive care patients undergoing mechanical ventilation.

Patients and methods

Entry to the study was by consecutive admission to the adult surgical intensive care unit (ICU) of a tertiary referral hospital. Selection criteria were a requirement for mechanical ventilation at the time of ICU admission and access to stomach contents by nasogastric tube. Admission and clinical progress data were collected without reference to laboratory results. Tracheal suction was applied by nursing staff using single use suction catheters, and a gloved-hand technique. In-line, enclosed suction devices were not used during this study. Ventilator filters were not placed between the Y-piece connector and the ventilator tubing during the study.

SPECIMENS

A complete specimen set was obtained early every morning, 7 days a week, until the patient died or no longer required mechanical ventilation. All specimens were collected by the same investigator (T. J. J. I.) after preparing specimen containers, undergoing a

thorough hand wash with chlorhexidine solution, and drying and donning of sterile gloves. The ventilator was then inactivated under the guidance of a member of the intensive care staff for the short time required to obtain bacteriological swabs. The sequence of specimen collection was in the opposite direction to the putative colonization sequence (i.e. from expiratory trap to stomach contents) in order to avoid bias caused by accidental carryover.

The ventilator trap in the expiratory limb of the ventilator tubing was disconnected briefly and a sterile dry cotton swab run around the inner circumference of the afferent limb of the trap. The Y-piece connector was then sampled, after disconnecting from the angle piece, by running a sterile dry cotton swab around its inner circumference. Next, the angle piece was removed briefly from the top of the tracheal tube and a dry, sterile cotton swab inserted without touching any surface other than the inside of the access port plug. A sterile swab was then run around the luminal circumference of the upper end of the tracheal tube. The connections and positioning of tubing were checked, and the ventilator cycle restarted. A specimen of gastric contents was obtained with a sterile 50-ml syringe via the nasogastric tube, after first discarding a smaller 10-ml syringe containing 5 ml or more of nasogastric tube contents. The previously used (early morning) tracheal suction catheter was kept for analysis by the attending intensive care nurse, who wrapped the catheter in her glove by turning the glove inside out during final removal. This specimen was placed in a self-seal bag, labelled and stored in the ICU specimen refrigerator if the other specimens had yet to be collected.

BACTERIOLOGICAL METHODS

Specimens were obtained for processing the same morning, other than those collected during weekends which were stored at 0–4 °C until the following Monday. Specimen recording, processing and further analytical work were performed without reference to clinical data. All results were withheld until after completion of the specimen collection phase of the study.

Each specimen was inoculated onto a single pre-prepared 5% horse blood agar 8-cm plate and an 8-cm MacConkey agar plate (Becton Dickinson, Heidelberg, Australia). Cotton swabs were applied and the inoculae spread following the conventional pattern. The lowermost 5 cm was cut from the tip of the tracheal suction catheter onto the blood agar plate using heat sterilized scissors, rolled to make a square impression. This was repeated on a MacConkey plate. The gastric contents specimen was mixed by repeated inversion and a 0.1-ml aliquot transferred by sterile pipette to the surface of the agar plate and spread with a sterile wire loop in the conventional manner. All plates were incubated for 18 h at 37 °C in air before examination. Any growth of gram-negative bacteria was noted and the colony isolated was identified to species level using standard methods.[17] Antibiotic susceptibility testing was performed on all isolates using the Kirby–Bauer method and NCCLS interpretation criteria.[18] Each isolate was stored by suspension in proprietary broth containing sterile beads (Microbank, USA) and frozen at −70 °C.

Molecular typing of isolates was performed on isolates resuscitated from the frozen culture collection by REP (repetitive extragenic palindromic) sequence analysis, as described previously,[9 19] but having adapted the method for use in capillary tubes with the rapid air thermal cycler.[20] Briefly, bacterial isolates were cultivated on nutrient agar at 37 °C for 48 h. A single colony of each isolate was picked off with a sterile toothpick and emulsified in 50 µl of sterile distilled water. The suspension was boiled for 5 min and then cooled on ice. A PCR mastermix was prepared in a laminar flow cabinet from 18 µl 10 × PCR reagent buffer (Promega, Madison, WI, USA), 18 µl of dNTPs 2 mmol litre^{-1} (Promega), 18 µl of 10% Triton X100 (Sigma Chemical Co., St Louis, MO, USA), 18 µl of sterile bovine serum albumin (Idaho Technology, Idaho Falls, ID, USA), 18 µl of dimethyl sulphoxide (E Merck, Darmstadt, Germany), 18 µl of $MgCl_2$ 10 mmol litre^{-1} (Idaho Technology), 18 µl of sterile distilled water, 25.2 µl of REP1-RI primer (5'IIIICGICGICATCIGGC-3', 500 mmol litre^{-1} stock solution) (Biosynthesis, Lewisville, KY, USA), 25.2 µl of REP2-I primer (5' ICGICTTATCIGGCCTAC-3', 500 mmol litre^{-1} stock solution) (Biosynthesis) and 18 ml of Taq DNA polymerase (8 µl of 5 u. ml^{-1} stock and 12 µl of enzyme diluent, Promega). Mastermix (10 µl) was dispensed into each pre-labelled sterile 1.5-ml Eppendorf tube, to which was added 1.2 µl of template DNA. After mixing, the reagents were drawn into a capillary reaction tube, the ends of which were heat sealed. The air thermal cycler (Idaho Technology) was programmed to run as follows: initial denaturation for 3 min at 95 °C, then 35 cycles of denaturation 0 min at 90 °C, annealing 1 min at 45 °C and elongation 8 min at 65 °C, with a final elongation at 65 °C for 16 min. Capillaries were then scored with a sapphire cutter and the contents dispensed into pre-labelled 1.5-ml Eppendorf tubes: 2-µl 5 × running buffer and dye were added to each tube and pipette mixed, and 12 µl of molecular marker (DNA 100 base pair ladder, Promega) and buffer were dispensed into the first of 15 wells in a 1% agarose (Sigma Chemical Co., St Louis, MO, USA) submarine gel, under Tris EDTA buffer. The amplified PCR product and buffer were dispensed into the remaining 14 wells and run at 100 V for 1.5 h. Staining was performed with ethidium bromide and visualization was with an ultraviolet transilluminator. The gel was photographed using Polaroid 667 film.

ANALYSIS

Isolates from different sites in the same patient, or the same site on different days, were regarded as possibly identical if the biochemical profile identified the same species, and antibiotic susceptibility differed by no more than one result. Isolates were referred to as identical only when amplified REP sequences produced an identical pattern on agarose gel electrophoresis. Identical first isolates from a given sample site were then plotted against the day the respective sample was collected.

STATISTICAL METHODS

The chi-square test was calculated using epidemiological software (C-stat, version 1.0, Cherwell Scientific, Oxford, UK) running under DOS 5.0. A threshold *P* value of 0.05 was used in assessments of statistical significance.

Results

Twenty consecutive patients admitted to the surgical intensive care unit were investigated (patient and clinical data are shown in tables 1 and 2). The proportion of patients and specimens from which gram-negative bacilli were isolated increased at successive sampling points in the specimen sequence followed (table 3). In seven patients and 12 series of isolates, gram-negative bacilli from more than one specimen site were identical by REP sequence analysis (table 4). In all seven patients and 12 bacterial series, the first isolate was obtained from a site within the patient, and in all but five instances the temporal sequence of isolation of a given REP sequence pattern was consistent with the proposed luminal route of bacterial colonization. However, in four series of identical bacterial isolates (three from one patient), isolates from the suction catheter tip or tracheal tube lumen antedated isolation of the same strains from the stomach contents. In one other patient, first isolation was at the angle piece and was followed by isolation from the suction catheter tip. No confounding colonization sequence involving more than two adjacent sites was observed.

Discussion

In this study of bacterial colonization in patients undergoing mechanical ventilation, the source of gram-negative species contaminating the proximal respiratory breathing system was the patient in every case where identical gram-negative bacilli were isolated from two or more specimen sites. There was no evidence to support progression of bacteria from the ventilator, or even carryover during the sampling procedure. On the contrary, the significant increase in gram-negative bacilli at successive sampling points implied that a colonization sequence that started in the ventilator tubing was unlikely, and was consistent with a progressive colonization of luminal surfaces in the opposite direction. In the majority of bacterial isolate series, the time of first isolation at a given site was consistent with the proposed luminal route of bacterial transfer, that is from the stomach contents via the oesophagus, into the trachea, down the outside of the tracheal tube and, on the suction catheter up into the tracheal tube, from where spread to the angle piece connector, the bifurcation of the Y-piece and finally the expiratory tubing could occur.

We did not attempt to determine if the oropharynx acted as a portal of entry, a secondary source of bacteria or a staging post in retrograde colonization, as resolution of the role of the oropharynx would have required sampling at multiple intra-oral sites. Instead, the study aimed to give equal prominence to the six locations sampled and to use rigorous bacteriological criteria to exclude similar but non-identical isolates. Inclusion of a genetic typing method in the assessment criteria necessitated exclusion of several possible isolate series, permitting a greater degree of confidence in the postulated colonization sequence.[21]

In five (25%) of the patients studied the gram-negative species concerned were observed first in the stomach contents. However, in two other patients the bacteria appeared first on the suction catheter tip, several days before the stomach contents. We have shown previously that gastric bacterial overgrowth may be intermittent in intensive care patients[22] but it remains possible that the gastric contents were contaminated by bacteria from the oropharynx, prior

gram-negative colonization at this site being common in hospitalized patients.[23] In two patients more than one gram-negative species followed the proposed colonization pathway. As the same phenomena appear to occur with different bacterial genera, much of the process of bacterial transfer from site to site could be explained by movement of fluids within the lumina of anatomical structures or respiratory devices.

Our observations are consistent with previous findings that the patient's end of the ventilator breathing system is more likely to be contaminated by gram-negative bacilli.[24] Moreover, these findings would suggest that the bacteria observed on the luminal surface of the tracheal tube originated in the patient's endogenous flora; either in the stomach contents, or possibly the oropharynx. If this is indeed the case, the suction catheter must be considered a means of transferring these bacteria and the other components of tracheal tube biofilm from the tracheal mucosa to the inside of the tracheal tube.[15] The subsequent dissemination of bacteria-laden particles from the luminal biofilm has to be inferred,[14 16] as direct observation is not possible *in vivo*.

The first point in the expiratory gas pathway that could act as an inertial impaction filter to trap aerosolized bacteria is where expired gases negotiate a 90° change in direction at the angle piece connector. The inner surface of the angle piece connector, where angle piece swabs were obtained, was therefore chosen as the most likely location for bacterial deposition after aerosolization of tracheal tube biofilm during the expiratory phase of ventilation. The presence of gram-negative bacteria on the inside of the angle piece in two isolate series after only 2 days, without identical isolates on the luminal surface of the adjacent tracheal tube, would therefore be consistent with aerosolization of bacteria during the expiratory phase of ventilation. Bacterial contamination of additional locations in the proximal respiratory breathing system prone to high velocity turbulent flow during the inspiratory phase of mechanical ventilation would be expected to increase the risk of dissemination of a bacteria-laden aerosol into the patient's lungs. The angle piece may have been a point of entry for bacteria subsequently isolated from the trachea in one case. If so, this may represent an isolated occurrence of exogenous colonization.

We have identified a possible route of bacterial colonization from the stomach via the tracheal tube and onwards into the ventilator breathing system. The results presented here prompt several important questions, particularly regarding the interaction between the suction catheter, tracheal secretions and the luminal surface of the tracheal tube. The extension of the so-called "retrograde" route of bacterial colonization of the ventilated lung proposed here should lead to additional target sites for preventive interventions, if our provisional conclusions are confirmed in further studies using other cohorts of intensive care patients.

Analysis of the EEG bispectrum, auditory evoked potentials and the EEG power spectrum during repeated transitions from consciousness to unconsciousness

R. J. GAJRAJ, M. DOI, H. MANTZARIDIS AND G. N. C. KENNY

Summary

We have compared the auditory evoked potential (AEP) index (a numerical index derived from the AEP), 95% spectral edge frequency (SEF), median frequency (MF) and the bispectral index (BIS) during alternating periods of consciousness and unconsciousness produced by target-controlled infusions of propofol. We studied 12 patients undergoing hip or knee replacement under spinal anaesthesia. During periods of consciousness and unconsciousness, respective mean values for the four measurements were: AEP index, 60.8 (SD 13.7) and 37.6 (6.5); BIS, 85.1 (8.2) and 66.8 (10.5); SEF, 24.2 (2.2) and 18.7 (2.1); and MF, 10.9 (3.3) and 8.8 (2.0). Threshold values with a specificity of 100% for a state of unconsciousness were: AEP index, 37 (sensitivity 52%); BIS, 55 (sensitivity 15%); and SEF, 16.0 (sensitivity 9%). There was no recorded value for MF that was 100% specific for unconsciousness. Of the four measurements, only AEP index demonstrated a significant difference ($P < 0.05$) between all mean values 1 min before recovery of consciousness and all mean values 1 min after recovery of consciousness. Our findings suggest that of the four electrophysiological variables, AEP index was best at distinguishing the transition from unconsciousness to consciousness. (*Br. J. Anaesth.* 1998; **80**: 46–52)

Keywords: brain, evoked potentials; monitoring, evoked potentials; monitoring, electoencephalography; monitoring, depth of anaesthesia; anaesthesia, depth

The ability to detect recovery of consciousness from a state of unconsciousness is an essential attribute for a monitor of depth of anaesthesia so that awareness during anaesthesia may be prevented. While an ideal method of assessment of anaesthetic depth remains an elusive goal, it has been suggested that monitoring of auditory evoked potentials (AEP)[1–3]or bispectral electroencephalographic (EEG) analysis[4–8] may be more reliable than other techniques. Recently, the AEP index (formerly known as the level of arousal score), a mathematical derivative which reflects AEP waveform morphology that is calculated from the amplitude difference between successive segments of the AEP curve,[9] has been investigated as a means of assessment of depth of anaesthesia.[10–12] Median frequency (MF)[13 14] and 95% spectral edge frequency (SEF)[7 15] of the EEG power spectrum have also been investigated for assessing anaesthetic depth and have been incorporated into commercially available monitors for this purpose.

In a recent study, our group observed that while the bispectral index (BIS) and to a lesser extent SEF correlated well with predicted blood concentrations of propofol during recovery from anaesthesia, AEP index was best at distinguishing consciousness from unconsciousness.[16] Therefore, this study was designed to investigate further the ability of AEP index, BIS, SEF and MF to identify awareness by their capacity to detect recovery of consciousness. We assessed changes in these electrophysiological measurements during alternating periods of unconsciousness and consciousness, the reproducibility of these changes in each patient and analysed the amount of inter-patient variability.

Patients and methods

After obtaining hospital Ethics Committee approval and informed consent, we studied 12 patients undergoing orthopaedic surgery (hip or knee replacement) under spinal anaesthesia. Two male patients and 10 female patients, mean age 73.8 (range 62–82) yr and mean weight 70.7 (55–84) kg completed the study. Patients with psychiatric or hearing abnormalities were excluded.

All patients were premedicated with temazepam 30 mg, 2 h before surgery. Spinal anaesthesia was produced with either 0.5% plain bupivacaine 3.0–3.5 ml or 0.75% plain bupivacaine 3 ml administered via a 26-gauge needle at the L2–3 interspace. An extradural catheter was also inserted for administration of top-up doses during surgery in prolonged cases.

After ensuring adequate regional anaesthesia for surgery, a target-controlled infusion (TCI)[17] of propofol was commenced and oxygen administered via a nasal sponge. One anaesthetist was responsible for standard monitoring of the patient and for manipulating the TCI of propofol to produce alternating periods of consciousness and uncon-

sciousness. Two investigators were present in addition to the anaesthetist responsible for conducting the anaesthetic. One investigator observed the AEP system and the EEG monitor, and recorded the timing of events such as onset of unconsciousness and consciousness. At intervals of 30 s, the second investigator established the presence or absence of an eyelash reflex and the patient's response to a verbal command to squeeze the investigator's hand. The transition from consciousness to unconsciousness was defined as the point at which loss of response to verbal command occurred, and the return of this response was considered the transition from unconsciousness to consciousness.

AUDITORY EVOKED POTENTIAL MONITORING

Auditory evoked potentials were monitored as described in our previous studies.[16 18] The EEG was obtained from three disposable silver–silver chloride electrodes (Zipprep, Aspect Medical Systems, USA) placed on the right mastoid (+), and middle forehead (−), with Fp_2 as the reference. The custom-built amplifier had a 5-kV medical grade isolation, common mode rejection ratio of 170 dB with balanced source impedance, input voltage noise of 0.3 μV and current input noise of 4 pA (0.05 Hz–1 kHz rms). A third-order Butterworth analogue band-pass filter with a bandwidth of 1–220 Hz was used. The auditory clicks were of 1 ms duration and 70 dB above the normal hearing threshold. They were presented to the right ear at a rate of 6.9 Hz. The amplified EEG was sampled at a frequency of 1778 Hz by a high accuracy, low distortion 12-bit analogue-to-digital converter (PCM-DAS08, Computer Boards Inc., USA) and processed in real-time by a microcomputer (T1950CT, Toshiba, Japan).

AEP were produced by averaging 256 sweeps of 144 ms duration. The time required for a full update of the signal was 36.9 s, but a moving time averaging technique allowed a faster response time to any change in the signal. Averaged curves were obtained at 3-s intervals.

The AEP index, which reflects the morphology of the AEP curves, allowed on-line analysis of the AEP. It is calculated as the sum of the square root of the absolute difference between every two successive 0.56-ms segments of the AEP waveform.[9] The AEP and other data were stored automatically on the hard disk of the microcomputer every 3 s, enabling future retrieval for further analysis.

EEG BISPECTRAL AND POWER SPECTRAL ANALYSIS

The EEG was obtained from four Zipprep electrodes placed on both sides of the outer malar bone (At_1 and At_2) with Fpz as the reference and Fp_1 as the ground. The EEG bispectrum, SEF and MF were monitored using a commercially available EEG monitor (A-1000, BIS 3.0 algorithm, rev. 0.40 software, Aspect Medical Systems, USA). The update rate on the bispectral index monitor was set to 10 s with the bispectral smoothing function switched off. Data from the A-1000 EEG monitor were down loaded automatically and stored on the microcomputer every 5 s.

Both monitoring systems (AEP and EEG) had sophisticated artefact rejection algorithms and the amplifiers of both also had medical grade isolation. Furthermore, the auditory clicks that produced the AEP generate signals 100 times smaller than the remainder of the EEG. Therefore, although the AEP and EEG were monitored simultaneously, there would have been no interference between the two systems that could have affected the results.

DATA ANALYSIS

Periods of consciousness and unconsciousness extended between the time of recovery of consciousness (response to verbal command) and the time when consciousness was lost (loss of response to verbal command). However, the periods from 1 min before until 1 min after transitions from one state of consciousness to the next were excluded when conscious and unconscious values of each measurement were analysed. These periods were excluded because they were likely to contain values representative of both consciousness and unconsciousness, as 36.9 s were required to obtain a full update of the AEP index (and 30 s for the BIS), and patients were also most likely to be drifting in and out of consciousness during these periods. Therefore, conscious values were considered to be those recorded during periods from 1 min after regaining consciousness until 1 min before the next loss of consciousness (fig. 1). Unconscious values were those recorded during periods from 1 min after loss of consciousness until 1 min before the next recovery of consciousness (fig. 1).

To investigate the ability of the electrophysiological variables to detect awareness, values recorded 1 min before recovery of consciousness were compared with values at 1 min after consciousness returned (fig. 1). All patients had at least three transitions from unconsciousness to consciousness. Therefore, the first three transitions were used to compare the ability of the different measurement systems to detect these transitions.

The mean (SD) and range of each measurement during all periods of consciousness and unconsciousness were determined by analysing all conscious and unconscious values, respectively, recorded over the course of the study. Measurements made during all periods of unconsciousness and consciousness were used to determine threshold values with 100% specificity and threshold values with approximately 85% sensitivity. Statistical analysis was with Minitab 10.5 for Windows, using ANOVA with Tukey's test. $P < 0.05$ was considered significant.

All patients were interviewed on the day after surgery for memory of intraoperative events. They were also questioned on their satisfaction with the auditory clicks and the technique of monitoring.

Results

Mean duration of surgery was 74 (range 58–121) min. There was a mean of 10 (6–20) periods of consciousness and unconsciousness.

AUDITORY EVOKED POTENTIAL INDEX

Table 1 shows the mean values for AEP index, BIS, SEF and MF recorded during all conscious or unconscious periods, as defined above. Table 2 shows

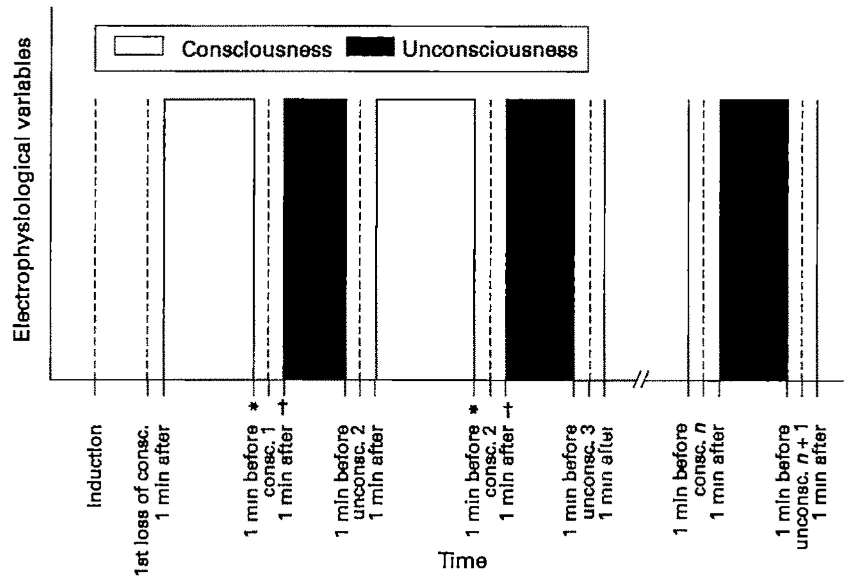

Figure 1 Periods when the four electrophysiological measurements (auditory evoked potential index (AEP index), bispectral index (BIS), spectral edge frequency (SEF) and median frequency (MF)) were analysed. All values recorded during periods of consciousness (consc.) and unconsciousness (unconsc.) were used to analyse the differences between the two states. Unconscious values of the four measurements at 1 min before regaining consciousness (*) were compared with conscious values at 1 min after regaining consciousness (†), at the first three transitions.

Table 1 Mean (range) values for the auditory evoked potential (AEP) index, bispectral index (BIS), 95% spectral edge frequency (SEF) and median frequency (MF) during consciousness (consc.) and unconsciousness (unconsc.)

	Unconsc.	Consc.
AEP index	37.6 (21–55)	60.8 (38–98)
BIS	66.8 (40–94)	85.1 (56–98)
SEF	18.7 (12.5–26.5)	24.2 (16.1–29.1)
MF	8.8 (1.7–13.7)	10.9 (1.5–18.9)

the threshold values of the four measurements with 100% specificity and threshold values with close to 85% sensitivity for states of consciousness and unconsciousness. In total, 4823 unconscious and 2055 conscious values of the AEP index, and 2885 unconscious and 1322 conscious values of BIS, SEF and MF were analysed. A threshold value of the AEP index of 37 had a specificity of 100% and a sensitivity of 52% for a state of unconsciousness. A threshold value of 56 was 60% sensitive and 100% specific for consciousness. Figure 2 shows the mean AEP index and BIS before and after the first three transitions from unconsciousness to consciousness. All mean awake values 1 min after return of consciousness were significantly higher than all mean unconscious values 1 min before ($P < 0.05$). AEP index values during periods of consciousness were more variable than values during unconsciousness (fig. 2, table 1).

Table 2 Values of the auditory evoked potential (AEP) index, bispectral index (BIS), 95% spectral edge frequency (SEF) and median frequency (MF) with 100% specificity and values with approximately 85% sensitivity for consciousness and unconsciousness

	Threshold	Sensitivity (%)	Specificity (%)
Unconscious			
AEP index	37	52	100
	44	85	87
BIS	55	15	100
	76	86	83
SEF	16.0	9	100
	21.0	85	92
MF	1.4	0	100
	10.7	85	55
Conscious			
AEP index	56	60	100
	45	87	85
BIS	95	14	100
	75	88	80
SEF	26.6	15	100
	21.9	84	92
MF	13.8	18	100
	7.9	85	25

BISPECTRAL INDEX

Table 1 shows that, unlike AEP index, some BIS values during unconsciousness were higher than the *mean* value during consciousness, and some conscious values were also lower than the *mean* value during unconsciousness. A BIS of 55 had a specificity of 100% but was only 15% sensitive for a state of unconsciousness (table 2). A very high value of 95 was required for 100% specificity for consciousness and was only 14% sensitive. Figure 2 shows the mean BIS at 1 min before and after the first three transitions from unconsciousness to consciousness. Unlike the AEP index, mean awake values 1 min after return of consciousness were not *all* significantly different from mean unconscious values 1 min before regaining consciousness ($P < 0.05$). BIS also contrasted with AEP index in that values recorded during unconsciousness demonstrated more inter-patient variability than values during periods of consciousness (table 1).

SPECTRAL EDGE FREQUENCY

Comparable with BIS but unlike AEP index, some SEF values during unconsciousness were higher than the *mean* value during consciousness, and some conscious values were lower than the *mean* value during unconsciousness (table 1). An SEF value of 16.0 Hz had a specificity of 100% but only 9% sensitivity for a state of unconsciousness (table 2). A value of 26.6 Hz was 100% specific but only 15% sensitive for

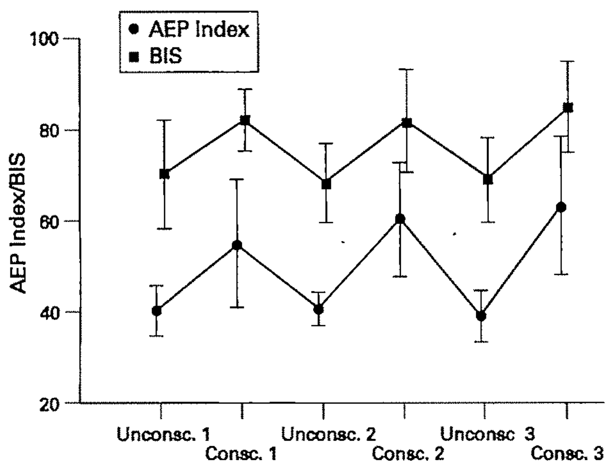

Figure 2 Mean (SD) auditory evoked potential (AEP) index and bispectral index (BIS) at 1 min before and after the first three transitions from unconsciousness (unconsc.) to consciousness (consc.). There was no significant difference between BIS at unconsc. 1 and consc. 2.

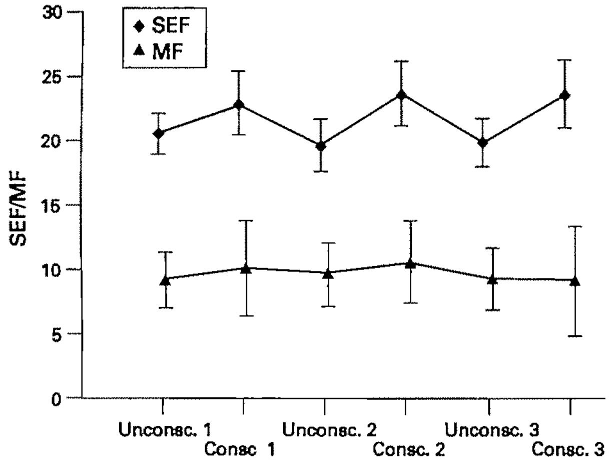

Figure 3 Mean (SD) spectral edge frequency (SEF) and median frequency (MF) at 1 min before and after the first three transitions from unconsciousness (unconsc.) to consciousness (consc.). There was no significant difference between SEF at unconsc. 1 and consc. 1.

consciousness. Figure 3 shows mean SEF and MF values at 1 min before and after the first three transitions from unconsciousness to consciousness. In common with BIS but unlike AEP index, mean awake values of SEF 1 min after return of consciousness were not *all* significantly different from mean unconscious values 1 min before regaining consciousness ($P < 0.05$). Similar to AEP index but unlike BIS, awake values of SEF were generally more variable than values recorded during periods of unconsciousness (fig. 3).

MEDIAN FREQUENCY

Similar to BIS and SEF, some values of MF during unconsciousness were higher than the *mean* value during consciousness, and some conscious values were lower than the *mean* value during unconsciousness (table 1). The lowest recorded awake value of MF was lower than the minimum MF value during unconsciousness (table 1) so that a value of 1.4 Hz, which was never attained, would have been 100% specific for unconsciousness (table 2). An MF value of 13.8 Hz was 100% specific but only 18% sensitive for consciousness. Figure 3 shows mean MF values at 1 min before and after the first three transitions from unconsciousness to consciousness. Although mean awake values of MF tended to be numerically greater than mean values during unconsciousness, all mean conscious and unconscious values were not significantly different. There was relatively large inter-patient variability for MF values during both consciousness and unconsciousness, and in common with AEP index and SEF but unlike BIS, this variability was greater during periods of consciousness (fig. 3).

No patient had recall of any event in theatre, including application of earphones and auditory clicks. All patients were satisfied with the anaesthetic technique and were happy to have the same technique of monitoring for any future anaesthetic.

Discussion

Although consistent changes (increased latency and decreased amplitude) in middle latency auditory evoked potential (AEP) waves occur as anaesthesia is deepened, it is difficult to analyse AEP waves in real time and to quantify changes in the clinical situation. The AEP index, a mathematical derivative that reflects AEP waveform morphology,[9] allows on-line assessment of the AEP during anaesthesia and surgery. Conventional EEG processing techniques such as those used to measure spectral edge frequency (SEF) and median frequency (MF) ignore the inter-frequency phase information in the EEG and may be unreliable for monitoring the level of anaesthesia because of the variable effects produced by different anaesthetic agents and the large inter-patient variability.[19] Unlike power spectrum analysis, bispectral EEG analysis also quantifies the phase coupling between component EEG frequencies.[20] The bispectral index (BIS), a numerical value derived from the EEG bispectrum, has been shown to have characteristics desirable in an anaesthetic depth monitor, such as the capacity to predict movement in response to surgery[4 21] and to detect consciousness[22-24] when using a variety of anaesthetic drugs.

The ability to distinguish consciousness from unconsciousness is an essential feature of a monitor of depth of anaesthesia, and was the clinical end-point used in this study, circumventing the problem of the absence of a universally accepted standard by which to compare such monitors under investigation.

The assumption that awareness, and therefore consciousness, is indicated by a response to command has been made in previous studies.[25 26] However, intraoperative awareness may occur without postoperative recall,[27] as occurred in all of our patients. Nevertheless, prevention of the dreaded consequence of intraoperative awareness without amnesia, especially in the presence of inadequate analgesia, is one of the most important functions of anaesthetic depth monitors. Amnesia for intraoperative events may have occurred in our patients because of the use of benzodiazepine premedication[28] or general anaesthetic drugs.[29 30]

Our study demonstrated the potential of the AEP index to detect recovery of consciousness. Of the four electrophysiological variables studied, only AEP

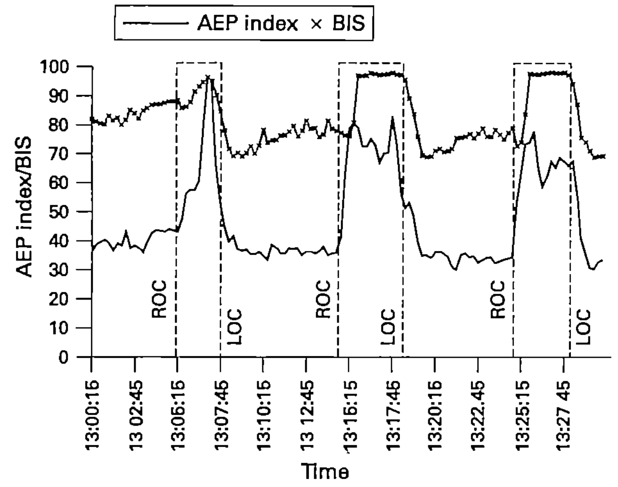

Figure 4 Changes in auditory evoked potential index (AEP index) and bispectral index (BIS) at recovery of consciousness (ROC) and loss of consciousness (LOC) for one patient in this study.

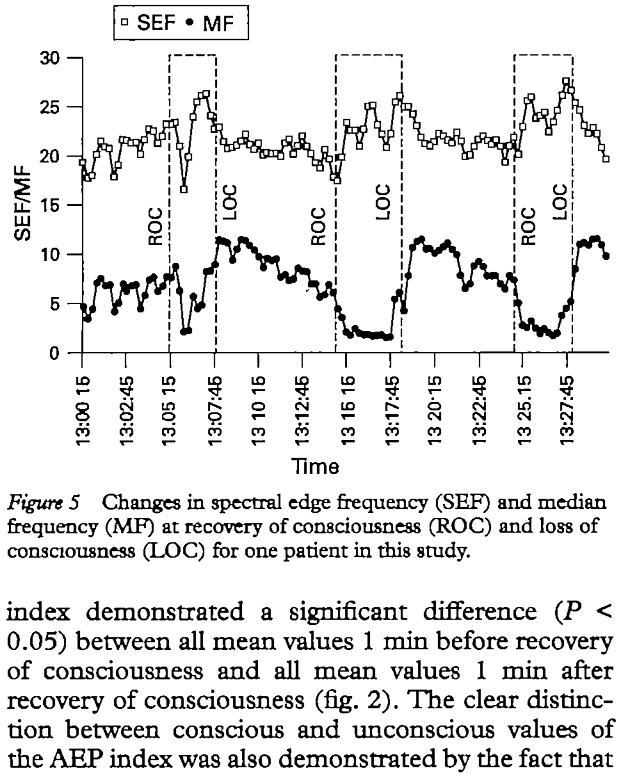

Figure 5 Changes in spectral edge frequency (SEF) and median frequency (MF) at recovery of consciousness (ROC) and loss of consciousness (LOC) for one patient in this study.

index demonstrated a significant difference ($P < 0.05$) between all mean values 1 min before recovery of consciousness and all mean values 1 min after recovery of consciousness (fig. 2). The clear distinction between conscious and unconscious values of the AEP index was also demonstrated by the fact that it was the only measurement in this study whose lowest recorded conscious value was higher than the mean unconscious value, and whose highest unconscious value was lower than the mean conscious score.

Although other studies[22-24] have shown BIS to be capable of detecting consciousness, in this study BIS was not significantly different when values 1 min before and after recovery of consciousness were compared. This could be explained by the gradual increase in BIS which frequently occurs during emergence from anaesthesia.[31 32] Values recorded 2 min apart (1 min before and after recovery) would therefore be more similar to each other than corresponding AEP index values, which increase suddenly at the time of awakening.[16] Figure 4, which shows changes in AEP index and BIS for one of the patients in our study, demonstrates this gradual increase in BIS during the first transition from unconsciousness to consciousness. In contrast, the AEP index increased sharply at all three transitions in this patient.

MF was least capable of distinguishing consciousness from unconsciousness, as all mean conscious and unconscious values were similar to each other (fig. 3). Studies by Schwilden and colleagues have suggested that MF values less than approximately 5 Hz indicate unconsciousness and that values of 2–3 Hz indicate a satisfactory depth of anaesthesia.[13 33-35] The difference between our findings and those of Schwilden and co-workers may be explained by differences in methodology and by the effects of EEG burst suppression which lead to misinterpretation of the EEG power spectrum.[36] In addition, there is possibly a lag between changes in MF and changes in anaesthetic concentration during recovery which could explain the *lower* values during conscious periods and *higher* unconscious values demonstrated in one of the patients in the present study (fig. 5).

The already low frequency of awareness during anaesthesia of 0.1%,[2 37] and the potentially disastrous consequences of its occurrence suggest that we should be attempting to develop monitors that will almost guarantee its elimination by reliably detecting unconsciousness. Such a monitor should be capable of providing information that is specific for unconsciousness at a level of anaesthesia that is not excessive. A BIS value of 55 was 100% specific but only 15% sensitive for unconsciousness (table 2). Additionally, a threshold value of 95 was necessary for 100% specificity for consciousness, as there were very high values of BIS recorded during periods of unconsciousness. These findings suggest that BIS could not be used to direct anaesthetic administration to *ensure* unconsciousness without the risk of excessive anaesthesia. Values of BIS which are specific for unconsciousness are not sensitive enough, and some adequately anaesthetized (clinically unconscious) patients have BIS values of fully awake subjects.

A similar problem of excessive anaesthesia may occur if SEF is used to ensure unconsciousness, as a value of 16.0 Hz was 100% specific but only 9% sensitive for unconsciousness. Very high SEF values were also recorded during unconsciousness so that a value of 26.6 Hz was necessary for 100% specificity for consciousness.

In contrast, an AEP index of 37 was 100% specific for unconsciousness, with a much greater level of sensitivity (52%) than corresponding SEF and BIS values. There was also no problem for unconscious patients with a very high AEP index, and a value of 56 was 100% specific and 60% sensitive for consciousness. These findings suggest that it may be possible to aim for an AEP index value that ensures unconsciousness while avoiding excessive anaesthesia.

The range of BIS values during periods of consciousness in this study varied between 68 and 98. Other studies have reported variable BIS values of approximately 50–85 at the time of recovery of consciousness.[8 16 22-24] Flaishon, Sebel and Sigl[23] reported that no unconsciousness was observed when BIS was greater than 70 and no consciousness occurred at values less than 65. In contrast, no consciousness was observed in this study at scores less than 55, while 36% of BIS values during unconsciousness (1048 of 2885 values) were greater than 70. The wide variation in BIS values between these studies may be a result of the use of different anaesthetic agents and different clinical end-points used to define consciousness.

Other studies have reported different results for SEF and MF during consciousness and unconsciousness. Median SEF was 20.4 Hz on recovery and 10.1 Hz during anaesthesia in one of the studies in Schwilden's series[35] compared with corresponding mean values of 24.2 and 18.7 Hz in this study. However, there was large variability in SEF values in both studies. Arndt, Hofmockel and Benad reported that adequate anaesthesia could be expected when SEF ranged from 14 to 16 Hz.[38] While an SEF value of 16 Hz was 100% specific for unconsciousness in our study (table 2), it was only 9% sensitive. Schwilden and colleagues also reported that no response to verbal command occurred at an MF value of less than 5 Hz for a variety of drugs.[33–35] In contrast, consciousness was present in the range 2–19 Hz in our study and, while 5 Hz was 94% specific for unconsciousness, it was only 7% sensitive.

This study demonstrated the potential of the AEP index to detect recovery of consciousness from propofol anaesthesia. Unconsciousness caused by different anaesthetic agents may produce dissimilar effects on the EEG[19 39 40] and on BIS,[21 41–44] although consistent changes have been demonstrated in MLAEP waves.[5 45–47] Further studies are therefore necessary to investigate the ability of these measurements to detect recovery of consciousness from anaesthesia produced by different drugs. Another limitation of this study was the lack of influence of surgical stimuli, effectively abolished by spinal anaesthesia, on the four measurements. Surgical stimulation is known to affect the EEG[48] and AEP.[48–50] However, it would be morally and ethically challenging to design a study in which consciousness was repeatedly induced in the presence of a painful surgical wound.

Acknowledgements

We thank Dr N. B. Scott and Dr P Ramayya for their assistance and Aspect Medical Systems for the loan of the A-1000 EEG monitor used in this study.

Comparison of pirenzepine, ranitidine, and pirenzepine–ranitidine combination for reducing preoperative gastric fluid acidity and volume in children

N. MAEKAWA, K. NISHINA, K. MIKAWA, M. SHIGA AND H. OBARA

Summary

We conducted a two-part controlled study to evaluate the efficacy of preoperative oral pirenzepine (muscarinic receptor antagonist known to inhibit gastric secretion), ranitidine, and the combination pirenzepine–ranitidine in controlling gastric fluid pH and volume in 210 ASA I children, aged 2–14 yr, undergoing elective surgery. In the first part of the study ($n = 90$), the proportion of children considered at risk for aspiration pneumonitis was reduced with pirenzepine 25 mg ($P < 0.05$) but not with 12.5 mg. In the second part of the study, the other 120 children were allocated randomly to one of four groups: pirenzepine 25 mg with placebo; ranitidine 75 mg with placebo; pirenzepine 25 mg with ranitidine 75 mg; and placebo and placebo. These medications were administered 1 h before anaesthesia. After tracheal intubation, volume and pH of the gastric fluid aspiration via a multi-orifice orogastric tube were measured. Pirenzepine 25 mg decreased gastric fluid volume ($P <$ 0.05) but failed to increase gastric pH. Ranitidine 75 mg increased gastric pH ($P < 0.05$) but failed to decrease fluid volume. The pirenzepine–ranitidine combination reduced gastric fluid acidity and volume ($P < 0.05$). (*Br. J. Anaesth.* 1998; **80**: 53–57)

Paediatric general anaesthesia is associated with a risk of pulmonary aspiration gastric contents[1] and the incidence of this complication is higher than in adults.[2] Many children arriving in the operating theatre have been shown to have a gastric fluid volume >0.4 ml kg^{-1} and a pH <2.5, regardless of the fasting interval.[3–6] Patients who fulfill these criteria are believed to be at increased risk of developing aspiration pneumonitis.[7] Several pharmacological interventions have proved successful in reducing the risk of lung damage by controlling gastric acid secretion, including H_2 histaminergic receptor antagonists and proton pump inhibitors.[1,3–6,8–13]

Pirenzepine, a selective M1 muscarinic receptor antagonist,[14] has been used extensively as an oral treatment for peptic and stress ulcers in adults.[15–17] The successful use of this drug in children with peptic ulcer[18,19] or for prevention of stress ulcer after paediatric cardiac surgery has been reported.[20] Pirenzepine i.v. before surgery in adults has been shown to reduce gastric secretion before anaesthesia.[21,22] However, there are no data on the efficacy of preoperative pirenzepine in controlling gastric fluid pH and volume in children.

Thus, the first aim of this study was to examine if preoperative oral pirenzepine reduces gastric fluid at induction of anaesthesia in paediatric patients. In adults undergoing surgery, concomitant use of pirenzepine and a H_2 receptor antagonist was superior to pirenzepine alone.[22,23] Therefore, the second aim of this study was to ascertain if a combination of pirenzepine and a H_2-receptor antagonist is more effective than each drug given alone in paediatric anaesthesia. We used ranitidine at a dose thought to be acceptable in children.[6,24]

Patients and methods

The study comprised two parts. Both were approved by the local Ethics Committee and parental informed consent was obtained for all children.

PATIENTS AND GROUP ASSIGNMENT

In part I, we examined the effects of pirenzepine on gastric fluid pH and volume in 90 healthy, ASA I children, aged 3–14 yr, undergoing elective (ophthalmological, otological, orthopaedic or urological) surgery. Patients with gastrointestinal disease, obese children who were more than 20% heavier than their ideal body weight and those receiving medications known to affect gastric fluid composition or gastric emptying were excluded. The children were allocated randomly to receive one of three medications ($n = 30$ in each group): placebo (group P_0), pirenzepine (Gastrozepin, Boehringer Ingelheim Japan, Kawanishi, Japan) 12.5 mg (group $P_{12.5}$) and pirenzepine 25 mg (group P_{25}). These medications were administered orally 60 min before induction of anaesthesia.

After confirmation of the effectiveness of pirenzepine 25 mg in reducing the number of children thought to be at risk of aspiration pneumonitis in part I of the study, we conducted part II to compare

the efficacy of pirenzepine, ranitidine and the combination pirenzepine–ranitidine in 120 children (2–14 yr). Inclusion and exclusion criteria were identical to those in part I. Patients were allocated randomly to one of four treatments (n = 30 in each group): placebo and placebo (group C), pirenzepine 25 mg and placebo (group P), ranitidine (Zantac, Glaxo-Sankyo, Tokyo, Japan) 75 mg and placebo (group R), and pirenzepine 25 mg and ranitidine 75 mg (group P-R). These medications were also given orally 60 min before induction of anaesthesia.

COLLECTION AND ANALYSIS OF GASTRIC FLUID

All children were prohibited from eating solid food or drinking milk products after 21:00 on the day before surgery, and were instructed to ingest a moderate volume (6–7 ml kg^{-1}) of clear fluid (tea, water or apple juice) until 3 h before anaesthesia. After preoxygenation with 100% oxygen by mask, anaesthesia was induced with nitrous oxide 4 litre min^{-1}, oxygen 2 litre min^{-1} and sevoflurane in gradually increasing concentrations up to 5%. Infusion of lactated Ringer's solution was started immediately after loss of consciousness. Atropine 0.01 mg kg^{-1} i.v. was administered through a three-way stopcock. The lungs were ventilated taking care to avoid inflation of the stomach. Tracheal intubation was facilitated by vecuronium 0.1 mg kg^{-1} i.v. All inductions were uneventful and there was no coughing, laryngospasm or vomiting during induction.

After tracheal intubation, a16-French gauge Argyle Salem Sump catheter was inserted into the stomach. Placement of the orogastric tube within the stomach was verified by auscultation over the epigastrium during introduction of 5–10 ml of air. Gastric fluid samples were obtained by gentle aspiration with a 50-ml syringe by an investigator who was unaware of the premedications given. Pressure was applied over the epigastrium with the patient supine and then in the left and right lateral decubitus positions to ensure maximum emptying of gastric fluid. Gastric contents were inspected visually for particles, and the volume of gastric contents was measured with the syringe. The pH of the gastric fluid was measured immediately using a pH meter (Horiba F-8L, Japan) which was calibrated using standard buffers at pH values of 1, 4 and 7. The pH meter has a precision of 0.01 pH units over the entire pH range. Age, weight, type and volume of clear fluid ingested, and gastric fluid pH and volume were recorded for each patient.

STATISTICAL ANALYSIS

Comparison of data between groups was made using one-way analysis of variance and Bonferroni correction for multiple comparisons of parametric data, while the Kruskal–Wallis rank test was used for non-parametric data. Differences between risk factors for the pulmonary acid aspiration syndrome were tested for significance using the chi-square test. $P < 0.05$ was regarded as statistically significant. Thirty patients in each group were sufficient to detect a difference of 0.7 between groups in gastric volume and pH at a significance level of 0.05 (=α), with a power of 0.85.[25]

Results

There were no differences between the seven groups in age, weight or type or volume of clear fluids ingested (table 1). Although gastric fluid was obtained from all children, the volume was sufficient for pH determination in 77 of the 90 samples and in 97 of the 120 samples in parts I and II, respectively. In the remainder, a very small quantity of gastric fluid remained in the gastric tube and could not be aspirated into the syringe. Such an insufficient quantity of gastric aspirate precluded measurements; these small quantities of gastric fluid were arbitrarily regarded as a residual volume of 0 ml. None of the children had particulate matter in the gastric aspirates. Adverse side effects (eruption, headache, diarrhoea or fever) related to pirenzepine or ranitidine were not observed before surgery.

PART I

As shown in figure 1, gastric fluid volume was less with pirenzepine 25 mg. The lower dose of pirenzepine failed to affect fluid volume significantly. Pirenzepine failed to decrease gastric fluid acidity significantly, regardless of dose. However, pirenzepine 25 mg significantly reduced the proportion of children considered at risk.

PART II

Pirenzepine alone and the combination pirenzepine–ranitidine significantly decreased gastric fluid volume but ranitidine alone did not. In contrast, ranitidine alone and pirenzepine–ranitidine increased significantly gastric fluid pH whereas pirenzepine alone did

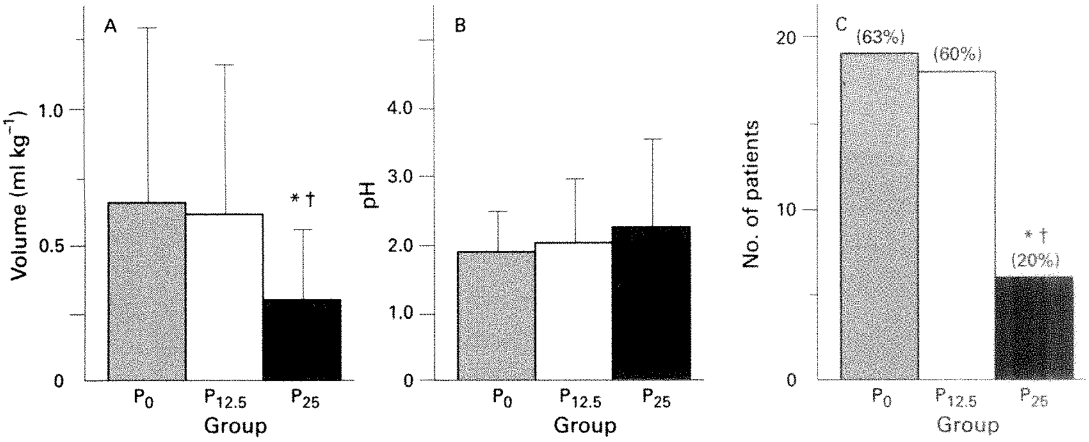

Figure 1 Gastric fluid analysis in part I of the study. Gastric fluid volume (A) and pH (B) are expressed as mean (SD). The percentage of children considered to be at risk of aspiration pneumonitis (C) (volume >0.4 ml kg^{-1} and pH <2.5) is shown in parentheses above each column. Group P_0 = placebo, group $P_{12.5}$ = pirenzepine 12.5 mg, group P_{25} = pirenzepine 25 mg. $^*P < 0.05$ compared with group P_0; $^\dagger P < 0.05$ compared with group $P_{12.5}$.

not. Gastric fluid volume and acidity in the pirenzepine–ranitidine combination group (group P-R) were significantly less than in all other groups (fig. 2). Ranitidine alone and pirenzepine alone reduced the proportion of children with a gastric fluid pH <2.5 and gastric fluid volume >0.4 ml kg^{-1}. Concomitant use of pirenzepine and ranitidine reduced the number of children deemed at risk to zero.

Discussion

Gastric secretion is regulated by nervous and hormonal mechanisms.[26] Nervous regulations act through the parasympathetic fibres of the vagus nerves, and hormonal regulation takes place mainly in response to gastrin. Receptors for histamine, acetylcholine and gastrin, all of which are stimulants for secretion of gastric acid, have been identified on the parietal cells in the gastric glands.[26]

Muscarinic cholinergic receptors are classified pharmacologically into three subtypes (M1, M2 and M3).[14] M1 receptors are found in ganglia and various secretory glands, M2 receptors predominate in the myocardium and also appear to be found in smooth muscle, and M3 receptors are located in smooth muscle and secretory glands. Pirenzepine has a high affinity for M1 receptors with low affinity for M3 receptors.[14, 15] The drug is thought to inhibit secretion of gastric juice mainly by blocking binding of acetylcholine to M1 or M3 receptors, although the precise mechanism is unknown. Although pirenzepine also combines with M1 receptor on the ganglia of the vagus nerve, the nerve-mediated mechanism probably has less involvement in the anti-secretory action compared with antagonism of the gastric gland itself. The specificity for the muscarinic receptors contributes to the advantages of pirenzepine, with little effect on the heart (tachycardia), eye (mydriasis), bladder (disturbed urination) or gut (constipation).[14, 27] Although the M1 subtype is found in the central nervous system (CNS), central effects of pirenzepine are not seen because of its low lipid solubility and limited penetration into the CNS.[15] The drug also inhibits secretion of gastrin, unlike omeprazole or H_2 receptor antagonists.[28] Pirenzepine has been shown to reinforce protective factors against gastric ulcer by increasing the blood flow of the gastric mucous membrane[29] and inhibiting reduction of gastric mucus production.[30] These characteristics may also give the drug additional advantages.

The rationale for the timing and doses of pirenzepine in our study were based on data from others. Onset of the gastric anti-secretory effect of pirenzepine occurs within 60 min after a single oral dose.[31] Pirenzepine has an accepted place in clinical practice for the treatment of severe gastritis and peptic ulcer in adults. For this purpose, pirenzepine 50–150 mg day^{-1} (1–2 mg kg^{-1} day^{-1}) given orally for several weeks of months is advocated.[16, 17] A single i.v. injection of pirenzepine 10 mg to adults has been used to prevent postoperative stress ulcer and is effective in reducing the number of patients at increased risk of the acid aspiration syndrome.[21, 22] The dose used in this study (12.5–25 mg) may be inappropriate in children because of morphological and pharmacokinetic factors. Pirenzepine 25–100 mg day^{-1} has been used in the treatment of gastric duodenal ulcer in children.[18] For control of long-term gastric pH after gastroduodenal ulcer haemorrhage in three children, pirenzepine 0.5–1 mg kg^{-1} day^{-1} was used.[19] No major adverse effects were observed. Although use of pirenzepine 50 mg may have been more effective, this large dose was not chosen to ensure safety in the initial evaluation of the effects of pirenzepine in this setting.

Reports on the effects of preoperative pirenzepine on gastric fluid in adults have been published. In all of these studies, premedication with i.v. pirenzepine successfully decreased gastric fluid volume.[21, 22] However, the effects on gastric fluid pH are conflicting. In several studies, pirenzepine failed to increase pH.[32, 33] Addition of other drugs (e.g. atropine or H_2 antagonists) to pirenzepine has been used successfully in adults to combat this drawback of pirenzepine.[21, 22] In this study, we observed phenomena similar to those in adult studies.

The efficacy of preoperative H_2 antagonists as acid aspiration prophylaxis has been demonstrated in children.[5, 6, 8-11] However, the reduction in gastric fluid volume is not a consistent finding in studies of H_2 antagonists, including ranitidine.[8-11] In our study, children who received ranitidine had gastric fluid volumes similar to those in the control group. The inability of H_2 antagonists to decrease gastric volume

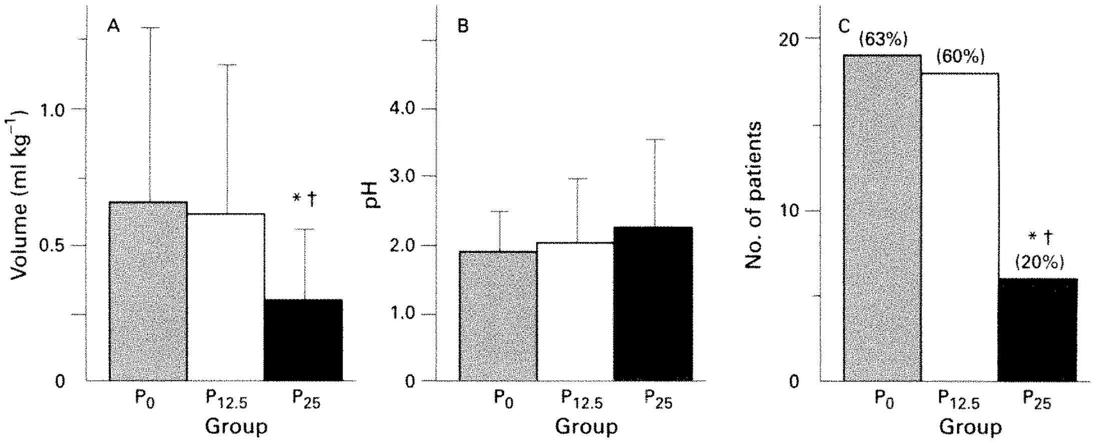

Figure 2 Gastric fluid analysis in part II of the study. Gastric fluid volume (A) and pH (B) are expressed as mean (SD). The percentage of children considered to be at risk of aspiration pneumonitis (C) (volume >0.4 ml kg^{-1} and pH <2.5) is shown in parentheses above each column. Group C = placebo and placebo, group P = pirenzepine 25 mg and placebo, group R = ranitidine 75 mg and placebo and group P-R = pirenzepine 25 mg and ranitidine 75 mg. $*P < 0.05$ compared with group C; $\dagger P < 0.05$ compared with group R; $\ddagger P < 0.05$ compared with group P.

may be a disadvantage compared with pirenzepine. However, because the risk of aspiration depends to a greater degree on gastric fluid pH, which is invariably increased by H_2 antagonists, than on volume, H_2 antagonists may be more suitable for prophylaxis than pirenzepine. In this study, we have shown that the pirenzepine–ranitidine combination reduced both gastric fluid volume and acidity, suggesting a potential use for this combination in clinical practice. However, these findings do not lead us to advocate this approach instead of rapid sequence induction in children at risk of aspiration pneumonitis.

In summary, we have shown that oral preoperative pirenzepine 25 mg (but not 12.5 mg) reduced gastric fluid volume in children but was ineffective in increasing gastric fluid pH to >2.5. In contrast, ranitidine 75 mg increased pH but failed to decrease volume. The combination of pirenzepine and ranitidine was superior to each drug alone for improvement in gastric fluid environment. In children who are at risk of aspirating gastric contents, the reduction in gastric fluid volume and acidity by this combined prophylactic intervention can reasonably be anticipated to provide protection against the occurrence of pneumonitis, should regurgitation and aspiration of gastric contents occur.

LABORATORY INVESTIGATIONS

Errors on anaesthetic record charts as a measure of anaesthetic performance during simulated critical incidents

A. J. BYRNE, A. J. SELLEN AND J. G. JONES

Summary

We have measured the performance of 10 trainee anaesthetists during a single simulated anaesthetic during which there was a complex critical incident. Errors in the recording on the anaesthetic charts of the "patient's" oxygen saturation, heart rate, systolic and diastolic arterial pressures and end-tidal carbon dioxide concentrations were used as a measure of mental workload and hence performance. The critical incident was designed to be stressful and contained, in sequence, episodes of hypotension, arrhythmia and bronchospasm. Chart recording errors increased markedly during the critical incident ($P < 0.01$) and decreased subsequently when the "patient" had stabilized. More than 22% of the values charted during the simulation were in error by more than 25% of the real value, and errors in excess of 100% of the actual value were recorded. There was no evidence of a tendency to consistently underestimate the magnitude of abnormal values. This method is appropriate for assessing the performance of groups of anaesthetists during simulated critical incidents. It also raises questions on the accuracy of anaesthetic record charts when recording critical incidents. (*Br. J. Anaesth.* 1998; **80**: 58–62)

Keywords: anaesthesia, audit; model, computer simulation; computers, simulation; anaesthetist, performance

"Mental workload" is a term often used to describe the amount of mental effort involved in performing any given task.[1] If we consider that there is a limit to the rate at which information can be processed by the human mind ("mental capacity"), then a simple model of mental workload is that it is a function of the proportion of this capacity in use at any time. The proportion of capacity in use varies depending on the difficulty or demands of the task. It is also generally accepted that as we acquire experience of a new task and develop procedural skills, the mental workload associated with that task decreases, because our capacity increases. For example, learner drivers need all their abilities just to keep the car on the road, while taxi drivers are able, with ease, to drive, eat, navigate and talk simultaneously. Studies in fields such as aviation have shown that high mental workload is associated with poor performance. Casali and Weirwille[2] noted that, "If requirements are moderately excessive, there may be a measurable degradation in the performance of simple, supportive tasks associated with flying, such as routine communications or engine instrument monitoring. Often, more immediate tasks receive the focus of attention, and other tasks are time shared or even ignored completely. Mental overload may further result in significant pilot errors in aircraft control, possibly culminating in an accident". The inference from these two observations is that a low mental workload during the performance of a complex task may be associated with expertise while a high mental workload for the same task may be associated with inexperience and loss of control. If the mental workload of a subject performing a standardized task can be measured, then it can provide an assessment of performance.

Several techniques have been used to measure mental workload, many relying on the use of a secondary task.[3] In such studies, the subject is asked to perform two tasks, a primary task (which is regarded as essential) and a secondary task (which has a lower priority). In this situation, the mental capacity of the subject must be shared between the two tasks. If a subject performs the primary task well, their mental workload is low, allowing spare capacity to be allocated to the secondary task. Conversely, if the subject performs the primary task badly, their mental workload is high and there is little spare capacity available for the secondary task. Thus performance on the secondary task can be used as an indication of how much spare capacity is available and is therefore a measure of the subject's performance in the primary task.

The problem with this type of research in anaesthesia is the difficulty in finding a secondary task which subjects repeat frequently enough to obtain good measures of performance, but which does not distort performance of the primary task (i.e. does not interfere with normal working patterns). The most common methods used in other fields have involved choice reaction time, memory, monitoring and tracking tasks.[3] In anaesthesia, Gaba and Lee[4] studied the workload of anaesthetists during real anaesthetic cases by asking them to add together two numbers on the screen of a computer every 45 s. They were asked to observe when the numbers

changed and enter their answer into the computer via the keyboard. The study showed that in times of stress, the anaesthetists took longer to add the numbers or failed to respond at all. Unfortunately, the addition of a monitor and a keyboard to an already complex theatre in addition to the risk of distracting the anaesthetist from their patient makes the technique unsuitable for routine use in real theatres. Further, the use of such techniques detracts from the realism of simulated events.

Our purpose in this study was to examine a secondary task technique, completion of the anaesthetic record chart, which can be more realistically incorporated into the simulation of an anaesthetic critical incident. This also has the potential of being used during anaesthetics involving real patients. During previous studies with the ACCESS[5 6] simulator we noticed that anaesthetists' perceptions of events during simulated anaesthetics were often very distorted.[7] In particular, when anaesthetists were asked to complete an anaesthetic chart after the simulation had finished, the charted values showed large errors and the time scale was overestimated by up to 100%. The errors we observed were similar to those detected during other studies involving measurement of mental workload.[3] It was therefore decided to investigate if chart error could be used as a measure of mental workload and hence performance.

Methods

Ten trainee anaesthetists completed a single simulation of an anaesthetic using the anaesthetic computer-controlled emergency situation simulator (ACCESS), a full scale, low-cost anaesthesia training simulator.[5] Each anaesthetist was introduced to the simulation as if taking over a routine case from a colleague. The "patient" was described as a 25-yr-old female undergoing an anterior cruciate ligament repair under general anaesthesia. She was said to be asthmatic and to be recovering from an episode of viral myocarditis. When the simulation was started, the anaesthetist was asked to behave as if it were a real case, including keeping an accurate, contemporaneous anaesthetic record, but they were not made aware of the purpose of the study. Two changes were made from previous simulations to aid the collection of data. First, the anaesthetic chart had a time scale marked at 2.5-min intervals rather than the usual 5 min to increase the number of data points. This increased the workload of those studied (as does any secondary task method), but we considered that it would not have significantly altered the result because completion of the anaesthetic chart is such a routine part of patient care during anaesthesia.[2] Second, the "patient" and monitors were set to continue through a series of abnormalities irrespective of any of the anaesthetists' actions. This ensured that all anaesthetists were exposed to exactly the same information from the simulator over the same time scale and that task demands would be held constant from simulation to simulation. The simulation lasted 25 min and started with 5 min of normal baseline readings. Hypotension then developed over the next 5 min with systolic arterial pressure decreasing from 90 to less than 60 mm Hg. A supraventricular tachycardia (SVT) of 160 beat min^{-1} then started and arterial pressure increased to normal. Five minutes later the SVT terminated and at the same time bronchospasm developed. After another 5 min, the bronchospasm reduced and the simulation ended with 5 min of "normality". Although the scenario seemed rather contrived, we have noticed during previous studies that those being tested become so involved in treating their "patient", that the behaviour of the simulator was rarely questioned. We expected therefore that the anaesthetists would treat each abnormality as it arose, as if it were a real case.

Table 1 Median errors for all 10 anaesthetists at the first time point

Variable	Median error
Heart rate	0.9 beat min^{-1}
Systolic/arterial pressure	5.4 mm Hg
Diastolic/arterial pressure	3 mm Hg
Oxygen saturation	0.3%
End-tidal carbon dioxide	0.08 kPa

At the end of the simulation each anaesthetist was allowed to enter any omitted data on their anaesthetic chart. A print-out of the values shown on the simulator's monitor was then obtained from the computer. The charted values of heart rate, systolic arterial pressure, diastolic arterial pressure, oxygen saturation and end-tidal carbon dioxide values obtained from the anaesthetic chart and the real values from the simulator print-out were compared and the difference between each of the paired (charted and real) values was calculated. To standardize the error for each variable, the median error for each of the variables was then calculated for all 10 anaesthetists at the first (2.5 min) time. These values are shown in table 1 and were taken to represent the performance of the anaesthetists in the unstressed, baseline state. All subsequent errors were divided by the baseline value to provide a standardized error. An error greater than 1 therefore represents a performance worse than baseline and less than 1 better than baseline. At each time the median standardized error, range and interquartile range for all 10 anaesthetists was calculated.

If a reading was missing from the anaesthetic chart it was allocated the same percentage error as the other readings at that time. If, at a particular time, none of the five variables was charted, it was assumed that the readings were unchanged from the previous entry and the error calculated accordingly.

To analyse the way in which anaesthetists were using each of the monitors, the data for each monitor were separated and the median standardized error for all 10 anaesthetists was calculated at each time. For statistical analysis, data for all variables for the first time were taken to represent the baseline, unstressed state. The median standardized error and interquartile range were then calculated. Data from the other times were classified into one of the four quartile ranges of the first time. This method was chosen because the data were positively skewed and so unsuitable for parametric analysis. A chi-square analysis was carried out, with $P < 0.05$ taken as significant. Manipulation of the data and drawing of the graphs were carried out using a standard spreadsheet (EXEL, Microsoft Corporation).

Table 2 An example of the data from a simulation completed by a single anaesthetist (see text for details of calculations)

	Time (min)

Results

All anaesthetists treated their "patient" in an appropriate manner and successfully completed the simulation. All anaesthetists eventually used a sympathomimetic drug to treat the hypotension. This treatment was then blamed for the production of the supraventricular tachycardia. Arrhythmia usually prompted discontinuation of the volatile anaesthetic and the resulting reduction in depth of anaesthesia was blamed for the bronchospasm. The final phase of normality was accepted as evidence of the success of the anaesthetist's treatment with either aminophylline, epinephrine or salbutamol.

Data from a single anaesthetist are shown in table 2. Data for all five variables were available from both the anaesthetic charts and the simulator in all cases. The real values shown on the monitors are at the top and the values charted by the anaesthetist are shown below. Calculations were performed as described in the methods section. For clarity all calculated values are shown as integers. Actual calculations were performed using a spreadsheet and the output imported directly into graph drawing software to produce the figures.

Figure 1 shows the median standardized error, interquartile range and range for the five variables, recorded by all 10 anaesthetists. There was a clear increase in median charting error with the onset of the critical incident and a subsequent decrease, although the range was wide. Compared with the results in the first time period, all subsequent results were significantly worse ($P < 0.01$).

Figure 2 shows the median standardized error for three of the variables, as charted by all 10 anaesthetists over the period of the simulation. The data for systolic and diastolic arterial pressures were intermediate and have been omitted for clarity. There was a wide variation in error, but interestingly, the error in charting heart rate was lower than that of end-tidal carbon dioxide during the normal, hypotension and arrhythmia phases. In contrast, during the episode of bronchospasm (from 15 to 20 min), the error in heart rate charting increased above that of end-tidal carbon dioxide.

Discussion

We have shown that it is possible to use error in anaesthetic chart recording as a measure of mental workload and hence performance. Importantly, the method is not intrusive and is less likely to interfere with the normal activities of anaesthetists than methods of measuring mental workload described previously. Our method avoids the inter-observer variability which caused problems with a rating scale tested previously by another group.[8] It also does not require the use of videotaping, which is expensive and time consuming to analyse.

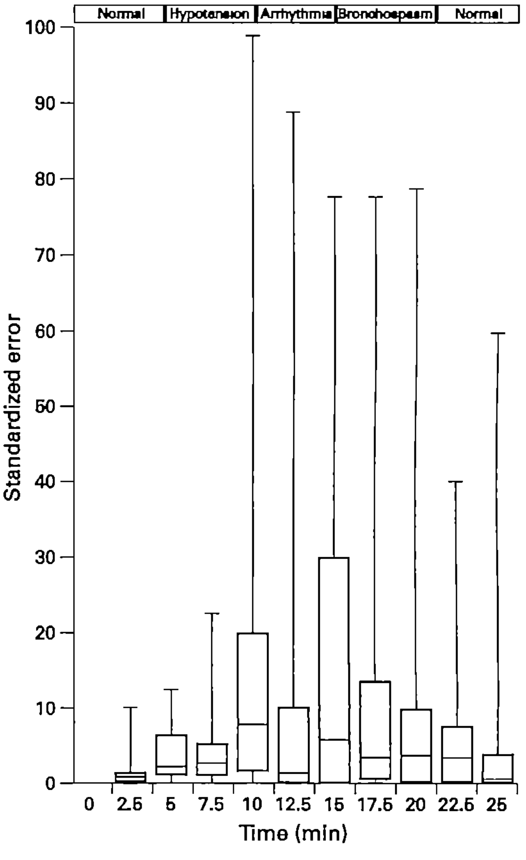

Figure 1 Median standardized error for all 10 anaesthetists during the period of the simulation (interquartile range, range).

This study may be criticized for not involving real anaesthetized patients and for not taking into account the many reasons why those studied may have chosen not to fill in the chart accurately. However, the secondary task method has been used in some industries for many years and has been shown to identify subjects who were subsequently successful in their jobs.[3] It has been suggested that one of the causes of error is the, possibly subconscious, reluctance of anaesthetists to chart abnormal values to avoid later criticism. However, examination of table 1 shows that where the error was greater than 10%, 11 of the charted values erred on the side of normality while 12 were more abnormal than the real values. This supports the view that errors are not introduced deliberately by the anaesthetist, but are caused by excessive mental workload. Another problem is that even with standardization, the variables studied have different normal ranges and variability so that, for example, an error in oxygen saturation of 10% may be considered to be much more significant than a similar error in systolic pressure, making comparisons between variables difficult. It is true that the errors for each of the variables studied are not directly comparable and simply standardizing the values results in loss of information. We suggest that interpretation of the results always requires a detailed knowledge of the circumstances under which the data were collected and of the psychological theory on which this method is based. However, our method has the advantage of producing a clear and easily comprehended result and the error of each variable can easily be studied individually if further information is needed.

The results in figure 1 show that chart error was clearly related temporally to the critical incident. This association was highly significant, even in this small study. However, the wide variability in error indicates that to provide a valid assessment of an individual, their performance over a range of tasks needs to be studied.

Figure 2 shows that the error was not divided equally between different monitored variables. Other research has indicated that, as situations become more complex and stressful, subjects tend to shed tasks and information so as to concentrate on what is perceived as important. It is interesting that the error in charting heart rate was generally low and then increased markedly during the period of bronchospasm, much more than that of end-tidal carbon dioxide. The inference is that the anaesthetists usually attended to the heart rate, but during a respiratory problem their attention was shifted elsewhere. This is perhaps unsurprising but almost impossible to quantify with any other method. The observation that charting error changes with the task suggests that it may be possible to assess new ways of presenting information during anaesthesia and allows the evaluation of new monitors without putting patients at risk.

As our previous study[7] indicated, our perception of events can differ widely from reality. While this study was designed to remove the previously demonstrated distortion of time associated with increased workload, we were still able to demonstrate an increase in chart recording error with the onset of a simulated critical incident. This is a strong indication that mental overload had occurred or was imminent in those tested. Solutions to such a problem are not clear at present. Techniques such as analysis of charting error may allow us to evaluate a variety of possible solutions in a scientific way. Thus if training and changes to equipment or the theatre environment lead to reduced mental workload, then it is likely that the chances of future errors is also reduced.

We must stress that the use of chart error is not necessarily appropriate for use in assessing the performance of individual anaesthetists, in real operating theatres, by retrospective analysis of their anaesthetic charts. First, the operating room is a complex environment and the care of the patient involves a variety of tasks, any one of which may rightly take precedence over completion of the anaesthetic chart. Second, the limitations of the monitors in current use may mean that we cannot always accept their output as a true reflection of the condition of the patient. Third, performance is not synonymous with competence. Poor performance cannot be equated with standards of patient care. However, this method might be applied to real anaesthetics, not for assessing individuals, but rather for assessing performance of groups of anaesthetists. For example it might be used to compare the results from a large group of anaesthetists across theatres, to assess the impact of equipment configurations or theatre layouts.

This study has another important implication. At present, the accuracy of the anaesthetic chart is important in the legal definition of acceptable standards of patient care. This study indicates that in a real critical incident, the accuracy of any anaesthetic chart is highly questionable. Further, the more stressful the situation, the less likely the chart is to be accurate. Thus the relevance of anaesthetic chart accuracy to the legal process must be questioned.

Finally, a recent editorial[9] commented that the increasing safety of anaesthesia is progressively reducing the value of studies such as the Confidential Enquiry into Maternal Deaths because deaths caused by anaesthesia have become so uncommon. To continue this progress, we need techniques which

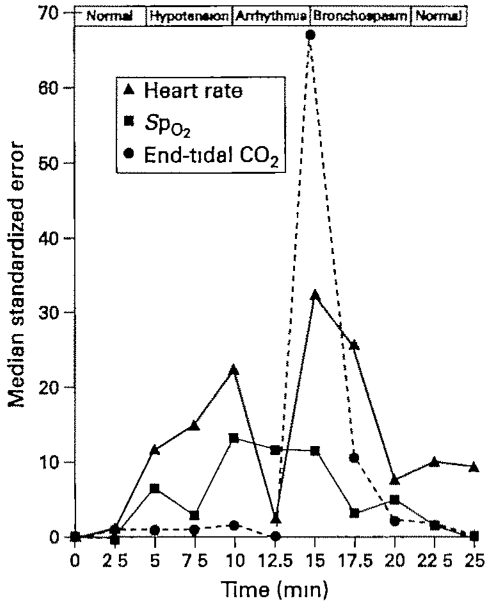

Figure 2 Median standardized error for three variables for all 10 anaesthetists during the period of the simulation. (Values for systolic and diastolic arterial pressures were intermediate and have been omitted for clarity.)

can detect poor performance even when it only has the potential to cause harm to patients. We believe that the use of secondary task techniques and chart error in particular may provide a way of assessing potential safety problems before errors and accidents occur.

Interactive effect of morphine and dexmedetomidine on gastric emptying and gastrointestinal transit in the rat†

T. Asai, W. W. Mapleson and I. Power

Summary

We studied the interactive effect of dexmedetomidine and morphine on gastric emptying and gastrointestinal transit in the rat. In one group of rats, to examine the interactive effect on gastrointestinal transit, the two drugs were injected i.p. in a fixed ratio (30: 1)—that of their ED_{50} values—in six doses (0.062–1.075 mg kg^{-1}), each to a different group of 5–8 male rats for each dose. In another group, to examine the interactive effect on gastric emptying, either dexmedetomidine or saline was injected with saline or with the ED_{25} or ED_{50} of morphine (0.22 and 2.8 mg kg^{-1}, respectively). In both groups, at 30 min, radiolabelled saline 1 ml was infused into the stomach; at 1 h, gastric emptying or gastrointestinal transit was calculated by measuring the radioactivity in the gastrointestinal tract. Morphine and dexmedetomidine produced a supra-additive inhibitory effect on gastrointestinal transit ($P = 0.02$). Dexmedetomidine 0.01 mg kg^{-1}, which itself significantly inhibited gastric emptying ($P < 0.01$), did not significantly alter the inhibitory effect of morphine on gastric emptying. Therefore, in rats, dexmedetomidine markedly enhanced the inhibitory effect of morphine on gastrointestinal transit, but it did not significantly alter the effect on gastric emptying. (*Br. J. Anaesth.* 1998; **80**: 63–67)

Opioids are used widely as powerful analgesics but they produce several side effects.[1] Alpha$_2$ adrenoceptor agonists reduce anxiety, induce sedation and analgesia, while producing less respiratory depression, nausea, vomiting and pruritus than opioids.[2 3] However, the use of alpha$_2$ adrenoceptor agonists may be limited because of their depressant effects on arterial pressure and heart rate.[4 5] Concurrent injection of drugs of different categories—such as an opioid and an alpha$_2$ adrenoceptor agonist—may reduce the required dose of both drugs, and thus may reduce the severity of complications associated with each drug. In addition, there has been considerable evidence that concurrent administration of a mu opioid receptor agonist and an alpha$_2$ adrenoceptor agonist produces supra-additive analgesia[6 7] and sedation.[8] In addition, there is some evidence for lack of enhanced respiration.[9–11]

In earlier experiments, we found that morphine strongly inhibited both gastric emptying and gastrointestinal transit to a similar degree, whereas the alpha$_2$ agonists, clonidine and dexmedetomidine, only weakly inhibited gastric emptying despite their marked inhibitory effect on intestinal transit.[12] Therefore, it is possible that concurrent injection of morphine and an alpha$_2$ agonist would produce marked inhibition of intestinal transit with relatively weak inhibition of gastric emptying. The interactive effects of a mu opioid receptor agonist and an alpha$_2$ adrenoceptor agonist on gastric emptying are not known.

The aim of this study was to examine the interactive effect of morphine and dexmedetomidine on gastric emptying and gastrointestinal transit of liquids in the rat.

Materials and methods

The study was conducted under the Animal (Scientific Procedures) Act 1986 (Home Office Licence: PPL 40/1397). Male Wistar rats, weighing 200–250 g, were housed under standard controlled environmental conditions, with a 12 h light–dark cycle. The animals were fasted for 24 h, but they were allowed free access to water until 20–30 min before the start of the experiment. Each animal was kept individually in a wire-mesh cage to prevent coprophagy during fasting. All experiments were started between 10:00 and 11:00. Dexmedetomidine (Orion-Famos Pharmaceuticals, Finland) and morphine (Sigma Chemical Co. U.K.) were prepared freshly on each day of the experiment.

A group of six rats was allocated for each study. If more than one rat was excluded, another group of six rats was used until a group was completed in which no more than one rat was excluded. Data from the non-excluded rats from all groups for each study (5–8 rats) were used.

Gastric emptying and gastrointestinal transit were studied separately in different groups of rats.

†Presented in part at the Anaesthetic Research Society, Leicester Meeting, March 20–21, 1997 (*British Journal of Anaesthesia* 1997; 79: 133P).

GASTROINTESTINAL TRANSIT

In one set of six groups of rats, the interactive effect of morphine and dexmedetomidine on gastrointestinal transit was studied. The two drugs were always injected in a fixed ratio (30:1)—that of their ED_{50} values obtained in earlier experiments (morphine 1.2 mg kg^{-1}; dexmedetomidine 0.04 mg kg^{-1}).[12] We used six different doses (0.062–1.075 mg kg^{-1}) which included the ED_{50} predictable on the basis of additivity.

GASTRIC EMPTYING

The inhibitory effect of dexmedetomidine on gastric emptying is weak.[12] Therefore, the interactive effect of morphine and dexmedetomidine on gastric emptying was studied in a separate set of six groups of rats. Three pairs of groups of rats received the following six combinations of drugs: pair 1:(1) saline and saline; (2) saline and dexmedetomidine 0.01 mg kg^{-1}; pair 2:(1) morphine 0.22 mg kg^{-1} (ED_{25}) and saline; (2) morphine 0.22 mg kg^{-1} and dexmedetomidine 0.01 mg kg^{-1}; pair 3:(1) morphine 2.8 mg kg^{-1} (ED_{50}) and saline; and (2) morphine 2.8 mg kg^{-1} and dexmedetomidine 0.01 mg kg^{-1}.

Gastric emptying and gastrointestinal transit were studied, as described previously.[12] In brief, at 0 min, a substance or a combination of substances (see below), in a volume of 1.0 ml kg^{-1} for each rat was given i.p. At 30 min, 1.0 ml of saline containing radiolabelled sodium chromate was infused into the stomach. At 60 min, the rats were killed, the stomach and small intestine removed, and the small intestine divided into 10 equal segments. Radioactivity in the stomach and each segment of the intestine was measured. If there was chyme in either the stomach or small intestine, the data were not used.

Gastric emptying and gastrointestinal transit (expressed in terms of the geometric centre) in each rat and percentage inhibition of gastric emptying or gastrointestinal transit for each drug were calculated.[12]

STATISTICAL ANALYSIS

Gastric emptying

The Mann-Whitney *U* test was used to test the effect of dexmedetomidine compared with saline on gastric emptying: on its own, in the presence of the ED_{25} dose of morphine and in the presence of the ED_{50} dose of morphine. Confidence intervals were calculated for median differences, between groups, for gastric emptying. $P < 0.05$ was considered significant.

Gastrointestinal transit

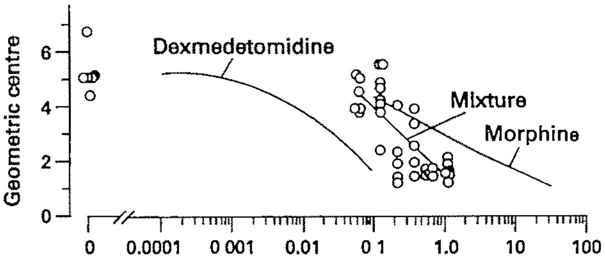

Figure 1 Effect of a mixture of morphine and dexmedetomidine on gastrointestinal transit of saline: values obtained from each rat (open circles), with fitted logit dose–response curves for the mixture and for each drug individually (the latter reproduced from Asai, Mapleson and Power[12]). The equation for percentage inhibition is $y = e^z/(1 + e^z)$, where $z = 1.011 + 2.226 \times \log x$ and x = dose of the test drug. The two drugs were always injected at a fixed ratio (30:1)—that of their ED_{50} values obtained in earlier experiments (morphine 1.2 mg kg^{-1}; dexmedetomidine 0.04 mg kg^{-1}).[12] Symbols were slightly displaced if there were similar values for any given dose. The values at zero dose are for the saline control.

The dose–response curve (variation of percentage inhibition with dose) of the 30:1 mixture of morphine and dexmedetomidine was modelled by fitting a sigmoid logit curve to fractional inhibition against log dose.[12] This was performed using the statistical package GLIM (generalized linear interactive modelling).[13 14] The output provided the information required to calculate the ED_{50} of the mixture, and hence the contribution from each component to that dose: 30/31 and 1/31 of the ED_{50} of the mixture for morphine and dexmedetomidine, respectively. The confidence limits of the ED_{50} of the mixture were obtained using the Fieller equation; the confidence limits of the doses of the two components were taken as 30/31 and 1/31 of those of the mixture. This was justified because the experimental error in making up the 30:1 mixture was negligible in comparison with the uncertainty in the ED_{50} values.

If the two drugs were simply additive, the concentration of each component of our fixed-ratio mixture required for 50% inhibition would be half the ED_{50} of the component on its own. The "theoretical" additive dose is then the sum of these two "half doses". Confidence limits of the components of this theoretical additive dose of the fixed-ratio mixture were determined by an adaptation (see appendix) of the method described by Tallarida, Porreca and Cowan.[15]

Results

GASTROINTESTINAL TRANSIT

Injection of the fixed-ratio mixture of dexmedetomidine and morphine produced a progressive dose-dependent inhibition of gastrointestinal transit (fig. 1).

An isobolograph[15 16] (fig. 2) showed that the required dose (P_1) was below the isobole. Although the confidence intervals for the components of the actual and theoretical additive ED_{50} values of the mixture overlap, the difference between the two ED_{50} values was significant (table 1). Therefore, morphine and dexmedetomidine produced a supra-additive interaction for the inhibitory effect on gastrointestinal transit.

GASTRIC EMPTYING

Dexmedetomidine alone significantly inhibited gastric emptying but when combined with morphine (ED_{25} or ED_{50}) the increase in inhibition was small and not significant.

Discussion

GASTROINTESTINAL TRANSIT

This study showed a clear supra-additive interaction between the effect of morphine and dexmedetomidine on gastrointestinal transit for a 30:1 mixture at the

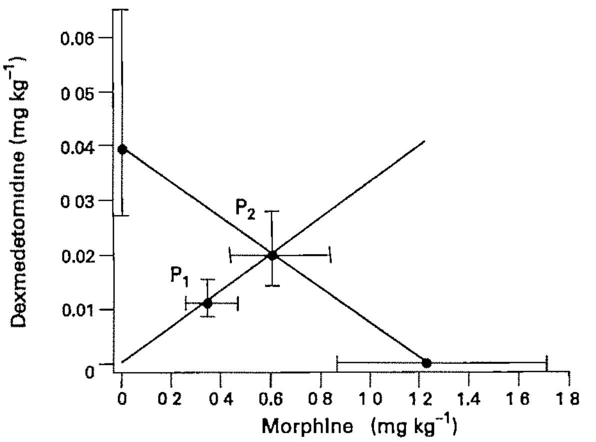

Figure 2 An isobolograph for the interaction of the inhibitory effect of morphine and dexmedetomidine on gastrointestinal transit. The downward sloping line (isobole) connecting the ED_{50} values of each drug separately is the theoretical additive line. The point (P_1) on the isobole is the theoretical additive ED_{50} of the mixture of the drugs (with 95%confidence intervals for each component). The actual ED_{50} of the mixture (P_2) (with 95%confidence intervals) is below the isobole, indicating that there is a supra-additive interaction for the inhibitory effect of these two drugs on gastrointestinal transit; difference in ED_{50} = 0.275, SE difference = 0.114, t = 2.4 (df 34), P = 0.02.

ED_{50} level. Results for mixtures of different ratios, or at other levels of effective dose, might have been different.

Puig, Pol and Warner[17] studied the interactive effect of clonidine and morphine on gastrointestinal transit (but not gastric emptying) in mice using a charcoal meal. They studied three dose levels (ED_{20}, ED_{50} and ED_{80}) for each drug separately, and three mixtures of the two, in the following proportions: "1:1" (equal fractions of the ED_{50} of each), "1:0.33" and "1:3". They found that with the 1:3 and 1:1 mixtures, concurrent injection of these drugs at their ED_{20} or ED_{50} values produced a supra-additive inhibitory effect (an additive interaction was observed with the 1:0.33 mixture). Our results are consistent with those of Puig, Pol and Warner.[17]

Puig, Pol and Warner[17] also claimed that a mixture of clonidine and morphine at higher doses (ED_{60} or ED_{80}) produced sub-additive interactions in inhibiting gastrointestinal transit. However, there are major inconsistencies between their tables and figures.[18] If their figures for ED_{60} and ED_{80} are re-plotted in accordance with the data in their tables, the mixture is (probably not significantly) supra-additive at ED_{60} and not significantly different from additive at ED_{80}.[18] Despite this uncertainty, it seems reasonable to conclude that at lower doses morphine and an alpha$_2$ adrenoceptor agonist (both clonidine and dexmedetomidine) may produce a supra-additive inhibitory effect on gastrointestinal transit. In addition, if higher doses of these drugs cause a sub-additive effect, this may not be clinically relevant.

GASTRIC EMPTYING

Mu receptor selective opioids markedly delay gastric emptying.[12 19] In contrast, alpha$_2$ adrenoceptor agonists have generally been reported to have either no or a weak inhibitory effect on gastric emptying,[12 20–22] although a strong inhibitory effect has been reported in some studies.[23 24] In this study, dexmedetomidine, which itself weakly but significantly delayed gastric emptying, did not significantly alter the inhibitory effect of morphine on gastric emptying.

Table 1 Theoretical additive ED_{50} and actual ED_{50} values, with their variances for the mixture of morphine and dexmedetomidine at a ratio of 30 : 1

	ED_{50} (mg kg^{-1})	Variance	Standard error	t	P
Theoretical	0.625	0.01019	—	—	—
Actual	0.351	0.00277	—	—	—
Difference	0.274	0.01296	0.1138	2.4	0.02

CLINICAL IMPLICATIONS

The incidence of diarrhoea is high (30–40%) in critically ill patients.[25 26] In these patients, gastric emptying is often delayed and consequently may increase the incidence of pulmonary aspiration of gastric contents.[27 28] One method of treatment for diarrhoea is to use drugs which delay intestinal transit and decrease the net secretion of fluid from the intestine. It is desirable to use drugs or combinations of drugs which achieve this without markedly delaying gastric emptying.

Opioids, such as codeine or loperamide, have been used widely as antidiarrhoeal drugs.[29 30] Alpha$_2$ adrenoceptor agonists also inhibit diarrhoea produced artificially by several substances, such as castor oil or prostaglandin E_1.[31 32] They also inhibit diarrhoea in animals with opioid withdrawal symptoms, produced by injecting a series of high doses of opioids and then injecting naloxone.[33 34] In patients, these agonists have been reported to be effective in inhibiting diarrhoea associated with several different diseases.[35 36]

Concurrent administration of an opioid and an alpha$_2$ adrenoceptor agonist produces a supra-additive antinociceptive effect,[6 7] sedation[8] and inhibition of gastrointestinal transit, but not respiratory depression[9-11] or gastric emptying. Therefore, concurrent administration of these drugs may be appropriate as antidiarrhoeal therapy; however, the use of this combination for pain management could be restricted by enhanced sedation and constipation.

In summary, we have shown that, in the rat, dexmedetomidine markedly enhanced the inhibitory effect of morphine on gastrointestinal transit, whereas it did not significantly alter the effect of morphine on gastric emptying.

Appendix

The Fieller equation provides a means of estimating the uncertainty of the ratio of two random, normally distributed variables. The input required includes the variances of the numerator and denominator; the output is in the form of asymmetric confidence limits.

Determination of the confidence limits of the theoretical additive ED_{50} of a mixture of two drugs requires application of the Fieller equation to a ratio in which the uncertainties in the numerator and denominator have been estimated by a previous application of the equation and are therefore in the form of asymmetric confidence limits, not of variances.

The approach described in detail by Tallarida, Porreca and Cowan[15] is to use an approximate form of the Fieller equation to yield a variance (implying symmetrical confidence limits), we adopted a different approach as follows.

When the variance of a parameter estimate is known, 95% confidence limits are calculated from $l_u = x + t_{\nu,0.05} \times$ SE and $l_l = x - t_{\nu,0.05} \times$ SE where l_u and l_l = upper and lower confidence limits, x = parameter estimate, $t_{\nu,0.05}$ = value of Student's t for ν degrees of freedom and $P = 0.05$, and SE = square root of the variance of the estimate. As can be seen, these limits are symmetrical. In addition, they can be rearranged to calculate back to the variance from the estimate and its confidence limits:

$$\mathrm{SE} = (l_u - x)/t_{\nu,0.05} \text{ and } \mathrm{SE} = (x - l_l)/t_{\nu,0.05}$$

Therefore, the variance of x, $V(x)$, the square of SE, is given by

$$V(x) = (l_u - x)(x - l_l)/(t_{\nu,0.05})^2$$

We used this last equation to provide an estimate of the equivalent variance of an input parameter to the Fieller equation when asymmetrical confidence limits of that parameter had been estimated by a previous application of the equation.

The fact that the confidence limits are asymmetrical indicates that the sampling distribution of the various ratios, and therefore of the numerators or denominators that they become, is not normal, as required by the Fieller equation, but skewed—positively skewed in all our examples. Therefore, the confidence limits and variances which we calculate from these initial confidence limits are approximate. However, when we applied our method to an example given by Tallarida, Porreca and Cowan[15] the result was indistinguishable from those indicated in the isobologram they used to display their results, even though those involved t values of only 4–5.

Also, as we showed in a previous study,[12] in the determination of the ED_{50} of a drug, the assumptions about the error distribution are not met in our method (logit curve plus binomial error) and even less so in the conventional method (logit transformation plus normal error). Accordingly, even the basic ED_{50} values, and especially their confidence limits, are approximate. Therefore we resorted to the "bootstrap" technique[37–39] as an alternative method of estimating the parameters of interest.

For each drug (morphine, dexmedetomidine and the fixed-ratio mixture) 1000 bootstrap samples were drawn, a logit curve was fitted to each one, and the ED_{50} was calculated and converted from log dose to actual dose to give 1000 ED_{50} estimates for each drug or mixture. The bootstrapping was performed separately for each dose so that each bootstrap sample contained the same number of data points for each dose as the original data set but generally contained other than one of each of the originals: none of some, one of some, two of some, and so on. With 3–12 data points at each dose, this gave far fewer than 1000 different bootstrap samples for each dose, but far more than 1000 possible bootstrap combinations of the samples from all doses. Indeed, there was a small percentage of identical ED_{50} values in the set of 1000 bootstrap estimates for each drug.

Finally, random samples from the morphine and dexmedetomidine sets were combined to give a set of 1000 theoretical additive ED_{50} values which in turn were combined with randomly selected bootstrap ED_{50} values for the fixed-ratio mixture to obtain the difference which provides a measure of the degree of supra-additivity.

The sets of bootstrap ED_{50} values for the individual drugs and for the fixed-ratio mixture gave medians that were within 2% of the original fitted ED_{50} values; the confidence limits (means of the 25th and 26th; and of the 975th and 976th ordered bootstrap sets) were all closer than those obtained by the Fieller equation (±20% to ±30% of the mean *vs* ±25% to ±60%). The difference between the bootstrap and Fieller estimates was 2% for the theoretical additive ED_{50} (CL ±20% *vs* ±30%) and 5% for the difference between the actual and theoretical additive ED_{50}, for the fixed-ratio mixture (CL ±50% *vs* ±80% leading to a P value for evidence of supra-additivity of <0.001 instead of 0.02).

It seems safe to conclude that the confidence limits and P value in the body of the article are, if anything, conservative estimates.

Acknowledgement

We thank Mr C Juniper, HNC, for his skilful technical assistance, Dr W. D. Evans, Department of Medical Physics and Bioengineering, for his advice and help in the use of the gamma counter, and Mrs P. de Souza, Department of Haematology, for providing the radiolabelled liquid. We also thank Orion-Famos Pharmaceuticals, Turku, Finland, for the generous gift of dexmedetomidine.

Effect of sevoflurane on spontaneous sympathetic activity and baroreflexes in rabbits

D. Ma, S. M. Sapsed-Byrne, M. K. Chakrabarti and J. G. Whitwam

Summary

Sevoflurane causes a decrease in mean arterial pressure (MAP). We have studied in anaesthetized rabbits its interactive effects on MAP, the autonomic nervous system and baroreflexes. During sevoflurane administration changes in renal sympathetic nerve activity (RSNA) and heart rate (HR) were observed: (1) when the normal decrease in MAP occurred; (2) when this was prevented by angiotensin II; (3) during a similar decrease in MAP induced by infusion of sodium nitroprusside (SNP) without sevoflurane administration; and (4) during pressor and depressor responses to phenylephrine and SNP. There was a reduction in MAP from 80 to 40 mm Hg after 1–4% sevoflurane without changes in HR, while RSNA remained unchanged only up to concentrations of 3% and was depressed by 37% ($P < 0.05$) with 4% sevoflurane. When MAP was maintained constant with angiotensin II, both HR and RSNA decreased, by 12% and 69%, respectively, after 4% sevoflurane ($P < 0.05$). A decrease in MAP of 40 mm Hg during infusion of SNP increased HR and RSNA by 22% ($P < 0.05$) and 150% ($P < 0.01$), respectively. At 2% sevoflurane, baroreflex sensitivity (i.e. ΔRSNA/ΔMAP and ΔHR/ΔMAP) was depressed by 36% and 57%, respectively, for the pressor effects of phenylephrine, and by 89% and 81%, respectively, for the depressor effects of SNP. We conclude that the baroreflexes continued to compensate for the effects of sevoflurane on sympathetic and cardiomotor activity with concentrations up to 3% and 4%, respectively. (*Br. J. Anaesth.* 1998; **80**: 68–72)

Keywords: anaesthetics volatile, sevoflurane; sympathetic nervous system; reflexes, barorecetor; rabbit

Sevoflurane causes a concentration-related haemodynamic depression, particularly of mean arterial pressure (MAP)[1] which normally activates baroreflexes to cause an increase in heart rate (HR) and sympathetic activity. Alternatively, sevoflurane could cause a decrease in HR and sympathetic activity as a result of its central effects. However, the peripheral, central and baroreflex effects of sevoflurane interact, but hitherto there has been little work on their relative contributions to its perceived effects on the circulation. For example, Saeki and colleagues showed that up to 1.25 MAC of sevoflurane did not produce significant changes in renal sympathetic nerve activity (RSNA) in rabbits.[2] In humans, sevoflurane, at concentrations of 0.4–1.2 MAC, did not affect sympathetic nerve activity supplying skeletal muscle.[3] Thus the limited data available could suggest that although sevoflurane depresses baroreflexes, they continue to respond to some extent to a reduction in MAP, thereby maintaining the observed stability of RSNA and HR.

In this study we have tested the hypothesis that baroreflexes, although depressed, maintain a response to a reduction in MAP sufficient to mitigate the depressant effects of clinically used concentrations of sevoflurane on the autonomic nervous system.

Materials and methods

GENERAL PROCEDURES

The study was approved by the UK Home Office (license PPL 90/00852). We studied 22 New Zealand White rabbits of both sexes, weighing 3.5–4.0 kg. Anaesthesia was induced with methohexital 10–15 mg kg^{-1} i.v. and maintained with 1% α-chloralose in an initial bolus dose of 30 mg kg^{-1} i.v., followed by a continuous infusion of 15–20 mg kg^{-1} h^{-1}. A tracheotomy was performed and the lungs were ventilated artificially (SLE 2000, SLE Ltd, UK) with oxygen-enriched air. Neuromuscular block was maintained using bolus doses of succinylcholine 2 mg kg^{-1} i.v. every 20–30 min. A femoral artery and vein were cannulated for recording arterial pressure, sampling of blood and infusion of 1% α-chloralose. The right and left marginal ear veins were cannulated, one for infusion of fluids and the other for administration of test drugs. Oesophageal temperature was measured with a thermistor (Yellow Springs Instruments, OH, USA) and maintained at 37–39°C using heating lamps under the surface of the surgical table when required. pH$_a$ and arterial blood-gas tensions were measured using a blood-gas analyser (Radiometer ABL 3, Copenhagen, Denmark), and were maintained constant and also within the ranges of pH$_a$ 7.30–7.40, Pa_{CO_2} 4.4–5.5 kPa and Pa_{O_2} 22.7–28.0 kPa by adjusting ventilation and occasionally, when necessary, administration of small doses of sodium bicarbonate. HR, MAP and RSNA were recorded continuously on a multi-channel recording

system and stored on disk for later analysis (Maclab 8, ADInstruments, Australia). Concentrations of sevoflurane were measured with a Capnomac II (Datex, Helsinki, Finland).

RECORDING OF RSNA

The right kidney was exposed retroperitoneally by a left flank incision. A fascicle of the renal sympathetic nerves, alongside the renal artery, was isolated, desheathed and cut distally, immersed in a mineral oil pool and mounted on silver–silver chloride electrodes for recording sympathetic activity. Signals from sympathetic nerves were preamplified (Tektronix 122, Beaverton, OR) and displayed on an oscilloscope (Tektronix 565, Beaverton, OR), and also monitored by an audiospeaker. The amplified signals were rectified and integrated with a 100 ms time constant (Neurolog NL90, Hertfordshire, UK). Both amplified and integrated signals were displayed on an oscilloscope and plotted with a thermal recorder (Gould 1602, Essex, UK). The total electrical activity of the rectified and integrated signals during 20-s periods was measured in arbitrary units. Data for processing used the average of three measurements in each data set and were expressed as percentages of control values.

EXPERIMENTAL PROCEDURE

The preparation was allowed to stabilize for at least 30 min after completion of surgery. Twenty-two animals were allocated randomly to one of four groups. In group I ($n = 7$), sevoflurane (Abbott Laboratories Ltd, Queensborough, UK) was administered at 1.0%, 2.0%, 3.0% and 4.0% expired end-tidal concentrations, each for 20 min. In group II ($n = 5$), sevoflurane was administered as in group I but hypotension was prevented by infusion of angiotensin II 0.08–14 μg kg^{-1} min^{-1} (Sigma, Poole, Dorset, UK) and MAP was maintained within control values throughout. Measurements were made at the end of the 20-min period of administration at each concentration, and 30 min after sevoflurane withdrawal. Group III ($n = 5$) received infusion of 0.1% sodium nitroprusside (SNP) to lower MAP to 30–40 mm Hg after which it was discontinued. Observations of HR, MAP and RSNA were made every 5 min during infusions of SNP and also 30 min after it was discontinued. Subsequently, HR and RSNA data were collected from this group at MAP values comparable with those in group I induced by 1%, 2%, 3% and 4% sevoflurane and also after recovery. Animals in group IV ($n = 5$) were used to measure baroreflex sensitivity by observing pressor and depressor responses to bolus injections of phenylephrine 0.5, 1, 2 and 4 μg kg^{-1} i.v. and SNP 2, 4, 8 and 16 μg kg^{-1} i.v., respectively, to produce dose–response curves.

Maximum changes in HR (ΔHR), RSNA (ΔRSNA) and MAP (ΔMAP) in response to different pressor and depressor doses of phenylephrine and SNP, respectively, were observed during a control period and again 20 min after administration of 1% and 2% sevoflurane. Baroreflex sensitivity was evaluated by relating ΔHR or ΔRSNA and ΔMAP, and also by calculating the ratio of the maximum changes in HR and RSNA to the maximum changes in MAP (ΔHR/ΔMAP and ΔRSNA/ΔMAP) produced by the largest doses of SNP and phenylephrine.

ANALYSIS OF DATA

All data were expressed as mean (SEM). Statistical analysis was performed by analysis of variance (ANOVA) followed, where indicated, by paired t tests. $P < 0.05$ was considered to be statistically significant.

Results

HR, MAP AND RSNA

Examples of recordings of RSNA, from individual preparations, during administration of sevoflurane or SNP alone, and also during sevoflurane administration when a decrease in MAP was prevented by an infusion of angiotensin II, are shown in fig. 1.

The effects of sevoflurane and SNP on mean HR, MAP and RSNA are shown in fig. 2A and B. It can be seen that sevoflurane, which caused a reduction in mean MAP from 80 to 40 mm Hg at 4% sevoflurane, did not change mean RSNA with up to 3% sevoflurane which then decreased to 63% of control values at 4% sevoflurane ($P < 0.05$), without any significant change in mean HR from the mean control value of 246 beat min^{-1}. In contrast, when SNP induced a decrease in mean MAP from 80 to 40 mm Hg, there was an increase in mean HR from 249 to 292 beat min^{-1} ($P < 0.05$) and mean RSNA by 150% of control.

The effects of sevoflurane on HR and RSNA when hypotension was prevented by an infusion of angiotensin II 0.08–14 μg kg^{-1} min^{-1} are shown in fig. 2C. It can be seen that mean MAP was maintained near 84 mm Hg (i.e. the control value), HR remained unchanged with up to 2% sevoflurane but decreased from the mean control value of 259, to 239 beat min^{-1} and 231 beat min^{-1} at 3% and 4% concentrations of sevoflurane, respectively ($P < 0.05$). Mean RSNA decreased significantly to 75% ($P < 0.01$), 65% ($P < 0.01$), 57% ($P < 0.01$) and 39% ($P < 0.001$) of mean control values at 1%, 2%, 3% and 4% sevoflurane, respectively.

BAROREFLEX SENSITIVITY

Typical examples of recordings during phenylephrine 4 μg kg^{-1} i.v. and SNP 16 μg kg^{-1} i.v. injections showing the effect of sevoflurane administration at 1 and 2% are illustrated in figure 3.

Dose–response curves for changes in mean HR and mean RSNA in response to the pressor and depressor effects of phenylephrine and SNP, respectively, are shown in fig. 4.

For further clarification, the effects of 1% and 2% sevoflurane on ΔHR/ΔMAP and ΔRSNA/ΔMAP at the maximum effect in response to the highest doses of phenylephrine (4 μg kg^{-1}) and SNP (16 μg kg^{-1}) are shown in fig. 5. It can be seen that 1% sevoflurane reduced mean ΔHR/ΔMAP and ΔRSNA/ΔMAP by 24% (ns) and 30% ($P < 0.05$) for the pressor effects of boluses of phenylephrine, and by 56% ($P < 0.05$) and 42% ($P < 0.05$) for the depressor effects of boluses of SNP, respectively; at 2% sevoflurane, the

A: Sevoflurane alone with an unmodified decrease in arterial pressure. B: Effects of sodium nitroprusside alone, at the same arterial pressures as those at equilibration with 1%, 2%, 3% and 4% sevoflurane, showing a typical baroreflex response with an increase in sympathetic activity. C: Effect of sevoflurane when the associated decrease in arterial pressure was prevented by infusion of angiotensin II.

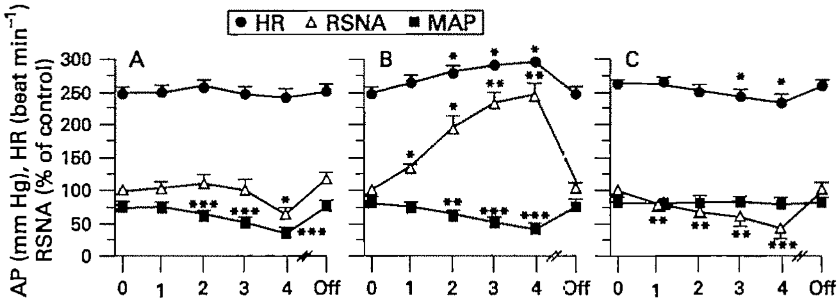

Figure 2 Effect of (A) sevoflurane ($n = 7$), (B) sodium nitroprusside (SNP) ($n = 5$) and (C) sevoflurane with angiotensin II i.v. ($n = 5$) on heart rate (HR), renal sympathetic nerve activity (RSNA) and mean arterial pressure (MAP) (mean (SEM)). B: Effect of SNP 0.5–8 μg kg^{-1} min^{-1} at comparable mean MAP values with those at equilibrium with 1%, 2%, 3% and 4% sevoflurane. C: Effect of sevoflurane on mean HR and RSNA when MAP values were maintained at control levels with infusions of angiotensin II 0.08–14 μg kg^{-1} min^{-1}. $*P < 0.05$, $**P < 0.01$, $***P < 0.001$ compared with control.

mean responses to phenylephrine were reduced by 57% for ΔHR/ΔMAP ($P < 0.01$) and 36% for ΔRSNA/ΔMAP ($P < 0.01$) and responses to SNP were reduced by 81% for ΔHR/ΔMAP ($P < 0.01$) and 89% for ΔRSNA/ΔMAP ($P < 0.01$).

Discussion

In this study 1–4% sevoflurane caused a concentration-dependent decrease in mean arterial pressure (MAP), without any significant change in mean heart rate (HR) while mean renal sympathetic nerve activity (RSNA), which remained unchanged up to 3% sevoflurane, decreased by 37% with 4% sevoflurane. In contrast, hypotension induced by sodium nitroprusside (SNP) caused major increases in both HR and RSNA. When the decrease in MAP, and hence compensatory baroreflexes, was prevented by angiotensin II, sevoflurane caused a progressive concentration-related depression of RSNA, but a significant decrease in mean HR occurred only at the highest concentrations of 3% and 4% sevoflurane. Although it was shown that sevoflurane caused a major reduction in baroreflex responses, it was concluded that they continued to compensate for its depressant effect on RSNA and HR with concentrations of up to 3% and 4%, respectively.

Saeki and colleagues reported that RSNA in rabbits was not influenced during sevoflurane administration up to 1.25 MAC.[2] A study in humans, in which direct recordings were made from nerve fibres in muscle sympathetic nerves, reported that the recorded activity remained unchanged during

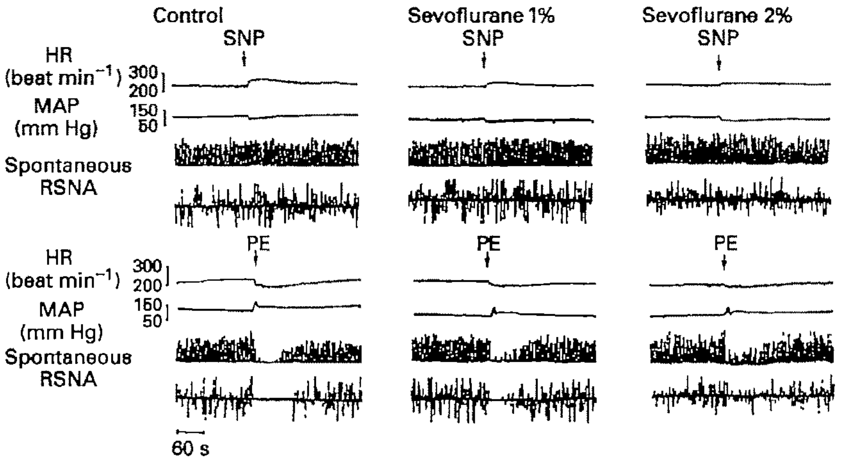

Figure 3 Example recordings of typical changes in heart rate (HR), mean arterial pressure (MAP) and spontaneous sympathetic nerve activity (RSNA· lower traces, directly recorded activity; upper traces, rectified integral) produced by the largest bolus injections of sodium nitroprusside (SNP) 16 μg kg⁻¹ i.v. and phenylephrine (PE) 4 μg kg⁻¹ i.v. (arrows), before and after equilibration with 1% and 2% sevoflurane.

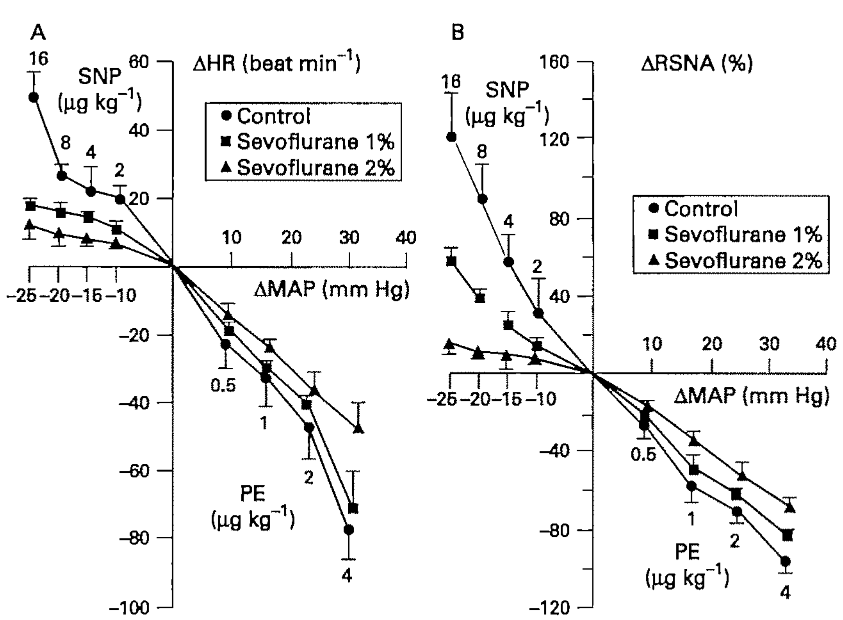

Figure 4 Relationship between ΔHR (A), ΔRSNA (B) and ΔMAP, caused by bolus injections of sodium nitroprusside (SNP) 2, 4, 8 and 16 μg kg⁻¹ i.v. and phenylephrine (PE) 0.5, 1, 2 and 4 μg kg⁻¹ i.v. before and after equilibration with sevoflurane in concentrations of 1.0% and 2.0% (mean (SEM), $n = 5$).

administration of sevoflurane in concentrations ranging from 0.4 to 1.2 MAC.[3] The results of our study showed that whereas concentrations of sevoflurane up to 3% (approximately MAC 1.5) caused no significant change in sympathetic activity, which is in keeping with previous work, a further increase to 4% (approximately 2 MAC) induced a significant reduction in RSNA.

Sevoflurane produced a concentration-related reduction in MAP, which is consistent with previous work.[1 4] Hypotension induced by sevoflurane results from both myocardial depression and a decrease in systemic vascular resistance.[1 5 6] Whereas a reduction in MAP caused by SNP induces typical baroreflexes with an increase in both RSNA and HR, the reduction in MAP caused by sevoflurane is not associated with such a response. When angiotensin II was used to maintain MAP constant, to examine the effects of sevoflurane uncomplicated by baroreflexes, it was found that sevoflurane caused a concentration-related depression of both RSNA and HR. However, previously it has been showed that angiotensin II itself may induce a degree of modification of baroreflexes.[7] For example the normal response to an increase in MAP, caused by peripheral vasoconstriction, is a decrease in both HR and sympathetic activity. During administration of angiotensin II in the rabbit, it has been shown that although there was a typical reduction in RSNA in response to the increase in arterial pressure,[8 9] it occurred without a significant change in HR.[7] In our study, when MAP was kept constant with angiotensin II, any observed changes in RSNA and HR could not be attributed to baroreflexes but indicated the unopposed direct effects of sevoflurane. Thus in the normal situation, without angiotensin II, a decrease in MAP would be expected to cause an increase in both RSNA and HR, which did not occur during sevoflurane administration in this study. However, although the studies when MAP was kept constant with angiotensin II clearly showed direct depression by sevoflurane of RSNA and HR, without further evidence one cannot comment on the degree of depression of the baroreflexes.

The effect of sevoflurane on baroreflexes was tested by observing the responses of RSNA and HR to the

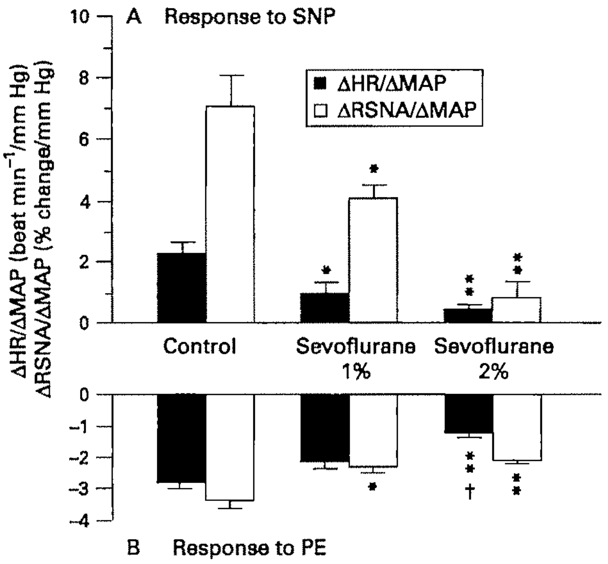

Figure 5 Changes in mean ΔHR/ΔMAP and mean ΔRSNA/ΔMAP induced by (A) sodium nitroprusside (SNP) 16 μg kg⁻¹ i.v. and (B) phenylephrine (PE) 4 μg kg⁻¹ i.v before and after equilibration with sevoflurane in concentrations of 1% and 2% (mean (SEM), $n = 5$). *$P < 0.05$, **$P < 0.01$ compared with control; †$P < 0.05$, 1.0% compared with 2.0% sevoflurane.

pressor and depressor effects of phenylephrine and SNP, respectively. It was demonstrated that baroreflex sensitivity, expressed as the relationship between changes in heart rate (ΔHR) and sympathetic activity (ΔRSNA), and ΔMAP (i.e. ΔHR/ΔMAP and ΔRSNA/ΔMAP ratios) was increasingly attenuated by an increase in sevoflurane concentration. However, whereas in depressor tests the ΔHR/ΔMAP ratio was depressed significantly throughout by sevoflurane, in pressor tests this ratio became significantly depressed only at the higher concentration of 2% ($P < 0.01$, fig. 5). These findings would support the traditional concept of Glick and Braunwald who suggested that whereas responses to increases in arterial pressure predominantly involved parasympathetic cardiomotor vagal activity, responses to decreases in arterial pressure were mediated principally by changes in sympathetic activity.[10]

In this study, the effect of sevoflurane at 3.0% and 4.0% on baroreflex sensitivity was not determined for two reasons. First, sevoflurane caused a major decrease in arterial pressure which prevented depressor tests without a serious risk to the viability of the preparations. Second, activity of the afferent fibres in the baroreceptor nerves is related to arterial pressure by sigmoid curves with the steepest part within the normal range of arterial pressures. This is reflected in rabbits in the relationship between RSNA and MAP which is also sigmoid and can be regarded as linear only for MAP values between 60 and 80 mm Hg.[11] Responses to changes in MAP outside this range do not provide a basis for comparison.

It is not known if there are specific sites in the baroreflex pathways which are depressed by sevoflurane. Saeki and colleagues suggested that sevoflurane, enflurane and isoflurane may act by direct depression of the central nervous system (CNS) or transmission in sympathetic ganglia rather than changes, for example, in the sensitivity of the aortic baroreceptors themselves.[2] Nevertheless, Seagard and co-workers reported that baroreceptor sensitivity is increased by both isoflurane and halothane.[12 13] From the data presented here it could be postulated that the absence of significant changes in RSNA at low concentrations of sevoflurane result from baroreflexes, albeit depressed, whereas the significant decrease in RSNA at higher concentrations is caused by direct depression of sympathetic pathways, for which the increasingly depressed baroreflexes can no longer compensate. Direct evidence of central depression was reported by Osawa and colleagues, who used the EEG to study the effect of sevoflurane on electrical activity in the CNS in cats and demonstrated that sevoflurane depressed the midbrain reticular neuronal activity in a concentration-dependant manner.[14] Although it has been reported that both halothane and isoflurane depress transmission in sympathetic ganglia,[12 13 15] as yet similar data have not been reported for sevoflurane.

In summary, although baroreflexes were depressed by sevoflurane, it appeared that they continued to compensate for the central depressant effects on RSNA up to concentrations of sevoflurane of 3% and cardiomotor activity up to 4%, which would provide an explanation for the apparent lack of effect of sevoflurane on the autonomic nervous system at low concentrations and validates the hypothesis tested in this study.

Effects of i.v. anaesthetic agents and halothane on [^{3}H]tetracaine binding to rat cerebrocortical membranes

M. KUDO, T. KUDO AND D. G. LAMBERT

Summary

In an attempt to determine if there is any overlap in local and general anaesthetic binding sites, we have examined the effects of thiopental, phenobarbital, pentobarbital, propofol, ketamine (racemic and R(+)/S(−)), alfaxalone, etomidate and halothane on [^{3}H]tetracaine binding to rat cerebrocortical membranes. Membranes were prepared in Tris HCl 50 mmol litre^{-1}, pH 7.4, by homogenization and centrifugation. Binding assays were performed in 1-ml volumes of Tris HCl buffer at room temperature or 37 °C for halothane. Binding of [^{3}H]tetracaine was displaced dose-dependently by unlabelled tetracaine with a mean pIC$_{50}$ value of 6.91 (SEM 0.07) (123 nmol litre^{-1}). With the exception of propofol (at high concentrations), all i.v. anaesthetic agents failed to displace the binding of [^{3}H]tetracaine. In contrast, halothane produced a dose-dependent and statistically significant reduction in total [^{3}H]tetracaine binding at clinically achievable concentrations (0.289, 0.885 and 1.484 mmol litre^{-1} equivalent to 1.0, 3.1 and 5.1 rat MAC) without markedly affecting the pIC$_{50}$. Collectively these data may suggest some overlap in the binding sites for [^{3}H]tetracaine and volatile but not i.v. general anaesthetic agents. (*Br. J. Anaesth.* 1998; **80**: 73–76)

Keywords: anaesthetics local, tetracaine; anaesthetics i.v.; anaesthetics volatile, halothane; model, rat; brain, cerebrocortex; theories of anaesthetic action, cellular mechanisms

We have shown previously dose-dependent and saturable binding of [^{3}H]tetracaine to rat cerebrocortical membranes. [^{3}H]Tetracaine binding was displaced dose-dependently by unlabelled tetracaine, procaine, lignocaine and prilocaine. Ropivacaine and bupivacaine were ineffective. In general, amino ester local anaesthetic agents displaced with the highest affinity.[1] In an attempt to determine the nature of the [^{3}H]tetracaine binding site we examined the effects of a range of ion channel blockers and neurotransmitters. With the exception of tetraethylammonium and 4-aminopyridine, all other non-anaesthetic agents failed to displace [^{3}H]tetracaine. These data may suggest an interaction with K$^+$ channels although it should be stressed that the interaction was weak.[1] Collectively these data confirm and extend previous studies using [^{3}H]tetracaine and [^{3}H]lignocaine[2–6] and imply that a single target site for all local anaesthetic agents is unlikely. To our surprise our previous study failed to show any displacement of [^{3}H]tetracaine with voltage-sensitive Ca^{2+} channel blockers,[1] despite the reported ability of local anaesthetics to displace [^{3}H]dihydropyridine binding to rat cerebrocortical membranes.[7]

In an attempt to further characterize the [^{3}H]tetracaine binding site we have examined the effects of a range of i.v. general anaesthetic agents (thiopental, phenobarbital, pentobarbital, barbituric acid, propofol, racemic ketamine, R(+) and S(−)ketamine, alfaxalone, etomidate) and the volatile anaesthetic agent halothane. The main aim of the study was to determine if there was overlap between the [^{3}H]tetracaine binding site and general anaesthetic binding site(s) in the CNS

Materials and methods

MEMBRANE PREPARATION

All studies were performed with membranes prepared from the cerebrocortex of female Wistar rats by homogenization and centrifugation, as described previously.[7 8] Briefly, the cerebrocortex was dissected from its internal structures, placed into Tris buffer 50 mmol litre^{-1}, pH 7.4, and homogenized using a Polytron (Maximum speed 3 × 10-s bursts) homogenizer. The resulting crude membrane homogenate was aliquoted at approximately 20 mg ml^{-1} and frozen until use (<2 weeks).

[^{3}H]TETRACAINE BINDING ASSAY

Binding of [^{3}H]tetracaine was performed in 1-ml volumes of Tris 50 mmol litre^{-1}, pH 7.4, for 1 h at room temperature.[1] (In halothane studies the incubation time was 45 min, see below.) Non-specific binding was defined in the presence of unlabelled tetracaine 1 mmol litre^{-1} and was typically less than 12%. The following agents were included in an attempt to displace [^{3}H]tetracaine binding: tetracaine 10^{-9}–10^{-5} mol litre^{-1}, thiopental 10^{-9}–10^{-4} mol litre^{-1}, phenobarbital 10^{-9}–10^{-3} mol litre^{-1}, pentobarbital 10^{-9}–10^{-3} mol litre^{-1}, barbituric acid 10^{-9}–10^{-3} mol litre^{-1}, propofol 1.5×10^{-9}–1.5×10^{-4} mol litre^{-1}, racemic ketamine 10^{-9}–10^{-3} mol litre^{-1}, R(+) and S(−)ketamine 10^{-9}–10^{-3} mol litre^{-1}, alfaxalone 10^{-9}–10^{-4} mol litre^{-1} and etomidate 10^{-9}–10^{-4} mol litre^{-1}. After incubation, bound and free radioactivity were separated by rapid vacuum filtra-

tion using a Brandel cell harvester onto Whatman GF/B filters. Filters were extracted overnight in Optiphase Safe prior to estimation of filter bound radioactivity.

VOLATILE AGENT DELIVERY

The effects of halothane were studied at 37 °C. Incubation buffer (0.9 ml) containing [^{3}H]tetracaine and unlabelled tetracaine were pre-equilibrated with halothane (1, 3 and 5atm% vaporizer setting) for 45 min using a 20-port manifold system to vented capped polypropylene tubes as described previously.[9] [10] Humidified air 2.0 litre min^{-1} delivered via a commercial aquarium pump was used as a carrier gas. The equilibration time of 45 min was determined empirically by measuring aqueous halothane concentrations at 1, 5, 10, 15, 30, 45 and 60 min at vaporizer settings of 1, 3 and 5atm% (n = 2, data not shown). Aqueous halothane concentrations (and equivalent atm% assuming that at 37 °C 1atm% would give an aqueous halothane concentration of 0.28 mmol litre^{-1}),[11] measured by gas chromatography[12] after a 45-min equilibration period are shown in table 1. After halothane equilibration, 100 µl of membranes (approximately 0.75 mg) were added and the incubation continued for another 45 min to allow the binding reaction to come to equilibrium, in the presence of either halothane or air. Bound and free [^{3}H]tetracaine were separated as described above. In all experiments a paired air and an ungassed control were included with each halothane concentration used.

DATA ANALYSIS

All data are presented as mean (SEM) (n). The concentration of displacing drug producing 50% displacement of specific binding (pIC$_{50}$) was estimated from individual curves by non-linear regression (GRAPHPAD-PRIZM).

Results

Binding of [^{3}H]tetracaine at room temperature was displaced dose-dependently by unlabelled tetracaine with a pIC$_{50}$ value of 6.91 (0.07) (123 nmol litre^{-1}), confirming our previous data (fig. 1).[1] With the exception of propofol at high doses (estimated pIC$_{50}$ 3.73 (0.02), 187 µmol litre^{-1}) all i.v. anaesthetic agents failed to displace binding of [^{3}H]tetracaine to rat cerebrocortical membranes (fig. 1, table 2).

Halothane produced a dose-dependent reduction in total specific [^{3}H]tetracaine binding compared with an ungassed control (fig. 2). There were no significant differences between total [^{3}H]tetracaine binding for ungassed control and paired air gassed control curves (halothane 0 mmol litre^{-1}, fig. 2D). Halothane produced a significant reduction in total binding at all (0.289, 0.885 and 1.484 mmol litre^{-1}) concentrations used. The pIC$_{50}$ was affected only by the highest concentration (1.484 mmol litre^{-1}, 5.29atm%), where a 1.63-fold rightward shift in the displacement curve was observed (table 3).

Discussion

We have demonstrated dose-dependent displacement of [^{3}H]tetracaine to rat cerebrocortical membranes by unlabelled tetracaine with a pIC$_{50}$ of 6.91 (0.07) (123 nmol litre^{-1}) consistent with previous reports.[1-6] With the exception of propofol (at high concentrations and hence with low affinity) all i.v. anaesthetic agents and barbituric acid failed to displace the specific binding of [^{3}H]tetracaine.

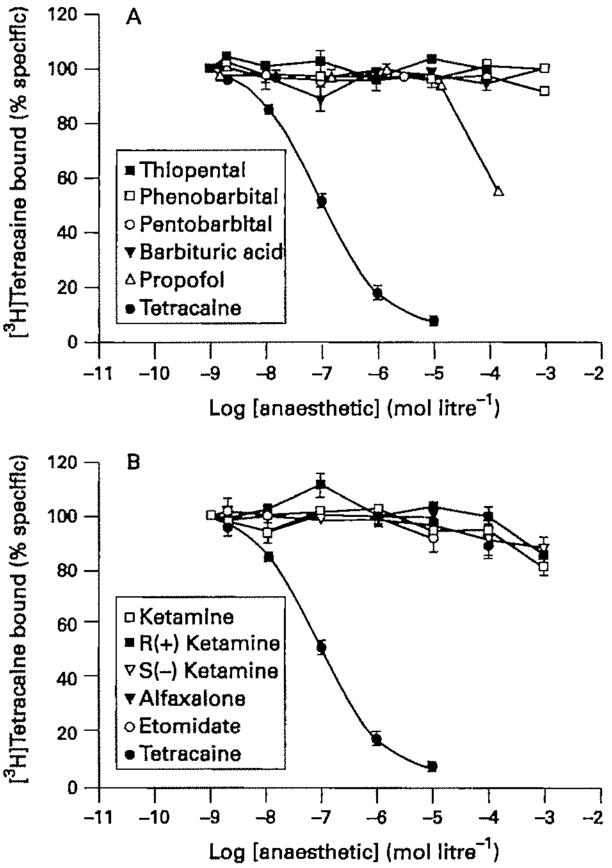

Figure 1 Effects of a range of anaesthetic agents on [^{3}H]tetracaine binding to rat cerebrocortical membranes. With the exception of tetracaine and propofol at high concentrations, there was no significant displacement. Data are mean (SEM) (n = 6–13) and all measurements were made at 20 °C.

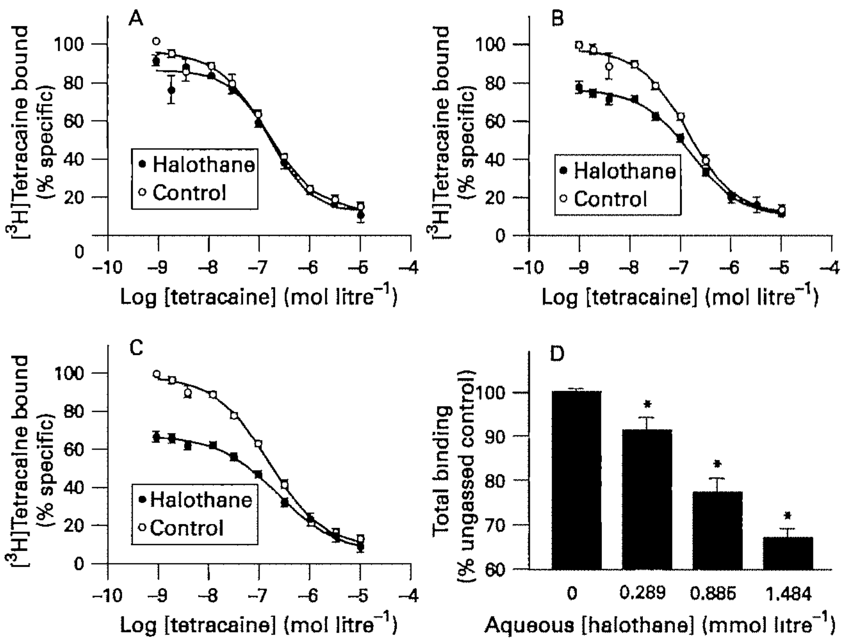

Figure 2 Effects of halothane on [^{3}H]tetracaine binding to rat cerebrocortical membranes Halothane produced a dose-dependent reduction (A: 0.289 mmol litre^{-1}, B: 0.885 mmol litre^{-1}, C: 1 484 mmol litre^{-1}) in total specific binding Data are mean (SEM) ($n = 6$) and all measurements were made at 37 °C. *$P < 0.05$, significantly reduced compared with paired air control

It is generally accepted that local anaesthetics depress neurotransmission by inhibiting neuronal Na$^+$ channels.[13, 14] However, it is also accepted that general anaesthetic agents do not produce significant Na$^+$ channel block and hence do not affect axonal conduction.[15] However, we have shown that [^{3}H]tetracaine was not displaced by tetrodotoxin (Na$^+$ channel blocker) and that a range of i.v. general anaesthetic agents also failed to displace [^{3}H]tetracaine. These data suggest that there is no direct overlap for the [^{3}H]tetracaine and i.v. general anaesthetic binding site(s). The voltage-sensitive Ca^{2+} channel represents a potential common target site for local and i.v. general anaesthetic agents. Both classes of agents inhibit the binding of [^{3}H]PN200–110 (a dihydropyridine) to L-type voltage-sensitive Ca^{2+} channels[7, 8] and inhibit Ca^{2+} flux through voltage-sensitive Ca^{2+} channels,[16, 17] although this is a controversial point that has received much attention.[17–19] This controversy is compounded by the observations that tetracaine displaces [^{3}H]dihydropyridine binding[7] when dihydropyridines fail to displace [^{3}H]tetracaine binding.[1]

In contrast with i.v. general anaesthetic agents, halothane at clinically achievable concentrations produced a clear and significant reduction in the binding of [^{3}H]tetracaine. However, the reduction in total specific binding at 1.02atm% (approximately 1.0 rat MAC[11]) was small (approximately 10%). The reduction in total specific binding without markedly affecting the pIC$_{50}$ (in the isotope dilution experiments presented in this study the IC$_{50}$ is equivalent to K_d as the concentration of [^{3}H]tetracaine was negligible) is consistent with halothane masking a proportion of the [^{3}H]tetracaine binding sites without affecting their binding properties. It is possible that [^{3}H]tetracaine could bind to two sites with differing sensitivity to halothane. However, close inspection of the curves in figure 2 do not support this notion as all had Hill slopes approaching unity. Volatile general anaesthetic agents interact with multiple targets within the CNS, including the well described GABA$_A$ receptor,[18, 20] excitatory transmission[21] and possibly voltage-sensitive Ca^{2+} channels.[17, 19] The data presented here suggest that there may be an overlap in the binding sites for volatile general anaesthetic agents and [^{3}H]tetracaine although the clinical relevance of these data are obscure.

Table 3 pIC$_{50}$ values for [^{3}H]amethocaine displacement curves in the presence and absence of halothane. Data are mean (SEM) (n=6). * $P < 0.05$ significantly greater than paired air control

Treatment	pIC$_{50}$	nmol litre^{-1}
Halothane 0.289 mmol litre^{-1}	6 81 (0 08)	155
Paired air control	6 69 (0 04)	204
Halothane 0 885 mmol litre^{-1}	6.84 (0 06)	143
Paired air control	6.87 (0.05)	135
Halothane 1 484 mmol litre^{-1}	6.61 (0 03)*	245
Paired air control	6.82 (0.03)	151

In conclusion, we have demonstrated that the binding of [^{3}H]tetracaine was unaffected by clinically relevant concentrations of i.v. general anaesthetic agents and reduced by halothane. The binding site or sites for [^{3}H]tetracaine remain to be determined and a “non-specific” binding site cannot be excluded.

REVIEW ARTICLE

Cytokines and adhesion molecules in acute brain injury

E. G. McKeating and P. J. D. Andrews

Once thought to be relatively shielded from the immunological and inflammatory processes which occur in the tissues of other body systems after acute injury, the brain participates actively in these processes. As a result of trauma, haemorrhage or ischaemia, injury to the brain releases mediators such as the cytokines which activate inflammation and cause further secondary brain injury. Intensive care physicians can do little to alleviate the gravity of the primary injury, but by understanding the mechanisms responsible for secondary injury, and how these mechanisms may, in future, be altered by drug therapy, they may be able to improve patient management and outcome.

A primary brain injury stimulates the cells of the central nervous system (CNS) to produce a variety of mediators. Laboratory and human studies have shown that there are at least three important cytokines which are released both by microglia and astrocytes after injury: interleukin-1β (IL-1β), tumour necrosis factor α (TNFα) and interleukin-6 (IL-6).[67, 68, 82] These proteins function as intercellular communication molecules and stimulate the reparative process which is termed gliosis. Gliosis, however, results in further production and release of cytokines by hypertrophied astrocytes and microglial cells, in addition to mediators released by cells of the peripheral immune system, such as polymorphonuclear cells (PMN), which migrate across a "leaky" blood–brain barrier. The net result may therefore be further damage to brain tissue. The first part of this review focuses on the parts played by these cytokines.

Leucocyte adhesion molecules, which are expressed on the surface of leucocytes and endothelial cells, control the migration of leucocytes into tissue. The expression of these molecules after brain injury is linked closely to cytokine production. They mediate toxicity in two ways: by causing leucocyte plugging of micro-vessels and by facilitating the release of toxic oxygen-derived free radicals by PMN which migrate into brain tissue as a result of adhesion molecule activity. The second part of this review focuses on the parts played by the adhesion molecules, intercellular adhesion molecule (ICAM)-1, E-selectin, L-selectin, P-selectin and the integrins in brain injury, and on the evidence linking the cytokines to adhesion molecule upregulation. Finally, we shall discuss if anti-cytokine or anti-adhesion molecule therapy may improve outcome after acute brain injury.

Keywords: polypeptides, cytokines; blood, adhesion molecules; brain, injury

Cytokines

The cytokines are low-molecular weight polypeptides which are synthesized and released by multiple cell types throughout the body. Their actions are numerous but they act primarily as mediators of the inflammatory process (either pro- or anti-inflammatory) and as growth factors. Many of the clinical signs which are seen after an acute brain injury (e.g. pyrexia, neutrophilia and cerebral oedema, secondary to disruption of the blood–brain barrier) are believed to be caused by cytokine activity.[76] Cytokines also stimulate the formation or release of many types of secondary mediators such as the oxygen-derived free radicals, neuropeptides and arachidonic acid derivatives, and upregulate the activity of the adhesion molecules. There is a great deal of overlap in the functions of these molecules, in particular between IL-1β and TNFα. Figure 1 summarizes the CNS actions of these cytokines.

INTERLEUKIN 1β AND TNFα

IL-1β and TNFα have similar local and systemic actions, which have been reviewed previously in the *British Journal of Anaesthesia*.[9, 91] Both cytokines have been implicated in the pathophysiology of disease states, including alcoholic liver disease, the systemic inflammatory response syndrome (SIRS), multiple trauma, burns and rheumatoid arthritis.[12, 24, 30, 63]

Experimental studies have shown that activity of both IL-1β and TNFα is increased within the first hours after a traumatic brain injury (TBI),[69, 102, 108, 111] and that microglia are a source of IL-1β,[33] which is a potent stimulant of gliosis.[34, 35] Cerebral IL-1β and TNFα are increased acutely after cerebral ischaemia in animal stroke models, particularly in the first hours after injury.[11, 60, 61, 100] These findings suggest that IL-1β and TNFα are released very early after injury, and explain partly why these two cytokines are often not detected in serum in clinical studies of brain injury.

Several laboratory studies have demonstrated the toxic effects of IL-1β and TNFα,[14, 71, 74, 105] although some investigators have used doses of cytokines well in excess of physiological concentrations. IL-1β acts to stimulate production of other cytokines, including TNFα,[18] and in particular IL-6, by both astrocytes and microglia.[2, 90] Similarly, TNFα causes the release of other cytokines, particularly IL-6.[2, 69, 90]

Altered EEG activity IL-1

Figure 1 Cytokine actions within the brain. All actions attributed to the cytokines are included, some of which may not be present *in vivo*.

There are fewer clinical studies which have implicated either IL-1β or TNFα in brain injury. IL-1β is increased in the cerebral cortex[77] and IL-1β receptor concentration is increased in cerebrospinal fluid (CSF)[65] after spontaneous subarachnoid haemorrhage (SAH). IL-1β is increased in the CSF of patients who have sustained a stroke,[101] while McClain and colleagues found increased IL-1β concentrations in ventricular fluid after a traumatic brain injury.[67] Serum TNFα is increased in patients with meningococcal infection, and the increase is more marked in those who are hypotensive.[105] Goodman and colleagues showed increased serum TNFα in 21 patients with traumatic brain injury, but serum concentrations did not correlate with outcome,[36] while Ross and co-workers showed that TNFα was present in the serum of 18 of 50 patients with a TBI.[82]

It is therefore apparent that both IL-1β and TNFα are important factors in the propagation of the inflammatory process in the early stages after a brain injury. We shall discuss the effects of IL-1β and TNFα on adhesion molecule expression later in this review.

INTERLEUKIN-6

IL-6 differs from IL-1β and TNFα in that it both causes and inhibits inflammation.[76 85] Akira, Taga and Kishimoto have published a comprehensive review which covers its functions in detail.[1] A particularly important function of IL-6 in brain injury is its action in increasing endothelial permeability.[64] There has been some debate about whether or not IL-6 is an active mediator in the inflammatory process after tissue injury or is simply a marker of injury severity,[8] but the evidence clearly implicates IL-6 in the pathophysiology of inflammatory brain injury.

Hariri and colleagues found increased IL-6 production by cultured human astrocytes after fluid percussion injury[40] and Shohami and colleagues showed increased IL-6 concentrations in contused rat brain, which peaked 8 h after injury.[94] Other investigators showed similar increases in IL-6 in experimental trauma models,[102 108 111] which usually lag behind the production peaks of IL-1β and TNFα.

There are many clinical studies which have investigated the role of IL-6 in brain injury. Osuka and colleagues investigated the theory that increased serum concentrations of IL-6 were related to brain tissue damage, and measured IL-6 concentrations in the serum of 70 patients after neurosurgery. They found an increase which peaked 24 h after surgery.[75] In a similar study, Heesen and co-workers showed that serum concentrations of IL-6 were increased after craniotomy, peaking 24 h after operation.[41] In 30 patients with a TBI, McClain and colleagues found increased serum concentrations of IL-6, which were highest on admission, together with greatly increased ventricular fluid IL-6. The decrease in serum IL-6 concentration correlated with clinical improvement, and concentrations decreased more rapidly in those with a Glasgow Coma Scale score greater than 8.[68] A recent study of 22 patients with TBI found increased ventricular fluid concentrations of IL-6, and that there is an association between IL-6 concentration and production of nerve growth factor.[51] Our group in Edinburgh measured arterial and jugular venous concentrations of IL-6 in 32 patients who had sustained either a TBI or spontaneous SAH and found increased systemic IL-6 concentrations, together with a marked jugular venous–arterial difference.[70] This suggests significant intracranial production of IL-6 after brain injury, and supports the experimental work discussed earlier.[40 94]

Clinical studies in non-traumatic brain injury further implicate IL-6 as a mediator in the secondary inflammatory response. IL-6 concentration is increased in the serum and CSF of stroke patients.[5 50 101] IL-6 and IL-8 concentrations in CSF are increased after SAH, peaking on day 6.[47 65] An interesting study by Amado and colleagues found that the concentration of IL-6 in patients' plasma increases at the time of diagnosis of brain death.[3]

As we have already discussed, IL-1β and TNFα, together with many other mediators, including platelet activating factor, interferon and the bradykinins, promote IL-6 production. The part played by IL-6 in the regulation of the intracranial inflammatory process is complex, because it has pro- and anti-inflammatory actions, and has a negative feedback effect on the production of IL-1β and TNFα,[85] but it occupies a central point in the web of mediators which control the inflammatory response to brain injury.

OTHER CYTOKINES

There have been several other cytokines implicated in the secondary inflammatory response after brain injury. IL-8[76 84 91] may function as a neutrophil chemoattractant (chemokine) after brain injury[6,109]; a recent study showed that concentrations of IL-8 were increased in the CSF of patients who sustained a TBI, and that this was associated with nerve growth factor production.[52] Expression of the macrophage inflammatory proteins MIP-1 and MIP-2 is increased after brain injury,[49,88] and there is increasing interest in the physiological role of the growth factors, including transforming growth factor (TGFβ) and fibroblast growth factor (FGF) in the antagonism of the secondary inflammatory process.[4,15,44,46,57]

Adhesion molecules

The leucocyte adhesion molecules are important control factors in the pathophysiology of secondary brain injury. There are three families of adhesion molecules.[51] The first includes the glycoproteins, L-selectin, E-selectin and P-selectin. L-selectin is constitutively present on the surface of leucocytes, while E- and P-selectins are expressed on the endothelial cell surface after injury. P-selectin is also expressed on platelets. The glycoproteins mediate the initial tethering of leucocytes to the vessel wall by binding to counter-receptors within moments of tissue injury.[98] Deficiency of either the selectins or their ligands causes failure of the migration process and recurrent infection.[28]

The two other families mediate strong adhesion and migration across the endothelium into tissues. The immunoglobulin "superfamily" consists of ICAM-1, ICAM-2 and vascular cell adhesion molecule (VCAM) 1, which are present on the endothelial surface, and ICAM-3 which is present on the leucocyte cell surface. Their counter-receptors form the third family, the integrins (e.g. CD11b, CD18, Mac-1) (fig. 2). The blood of healthy humans contains soluble, active forms of the selectins and immunoglobulins (termed sL-selectin, sICAM-1).[86]

This review focuses on those molecules which have been studied most closely in brain injury, namely ICAM-1, E- and L-selectin and the integrins. As the functions of the three families are similar, we shall consider them as a group for the remainder of this review.

RELATIONSHIP BETWEEN CYTOKINES AND ADHESION MOLECULES

Experimental work suggests that IL-1β, IL-6 and TNFα upregulate the activity of the adhesion molecules: one early study showed that treatment of endothelial cell cultures with IL-1β caused increased PMN adhesion by acting on endothelial cells.[7] IL-1β increases ICAM-1 expression in fibroblasts, and IL-1β and TNFα increase ICAM-1 expression in hepatocyte cell lines.[27,54] Hahne and colleagues discovered that TNFα induced expression of several types of adhesion molecule in mouse endothelioma cells: ICAM-1, VCAM-1, E-selectin and P-selectin.[37] Kukielka and co-workers published findings on the relationship between IL-6 and upregulation of ICAM-1 in the pathophysiology of reperfusion injury in the myocardium.[53] They showed that IL-6 mRNA expression was increased in a canine myocardial reperfusion model, and that this was followed by an increase in ICAM-1 expression in the same segments. In a clinical study which examined 22 patients admitted to the ICU with illnesses resulting from liver cirrhosis, leucocyte expression of the integrins CD11b and CD35 correlated with the concentration of IL-6 in plasma.[81]

It is apparent therefore that the cytokines are important regulators of adhesion molecule activity in non-neurological disease, and further experimental studies which examined brain tissue add weight to this important relationship in brain injury. TNFα and interferon-gamma cause induction of ICAM-1 expression in microglia,[114] and administration of TNFα to cultured CNS endothelial cells causes increased expression of VCAM-1 and E-selectin.[26] Similarly, IL-1β ,TNFα, interferon-gamma and lipopolysaccharide (LPS or endotoxin) increase ICAM-1 expression.[107] Rieckmann and colleagues found increased expression of ICAM-1 in human brain tissue sections after stimulation with TNFα and LPS,[79] but Shrikant and co-workers were unable to show an effect of IL-6 on ICAM-1 expression in astrocytes or microglia.[95] Although findings are occasionally contradictory, they strongly suggest that the increased concentrations of cytokines seen after acute brain injury upregulate the activity of adhesion molecules in the CNS, causing PMN infiltration and further cellular damage (fig. 3). In the next section we examine more closely the adhesion molecules, and the part they play in brain injury.

ADHESION MOLECULES AND BRAIN INJURY

Clinical research into the role of adhesion molecules in disease is still in its infancy, particularly in acute brain injury, but many studies suggest that manipula-

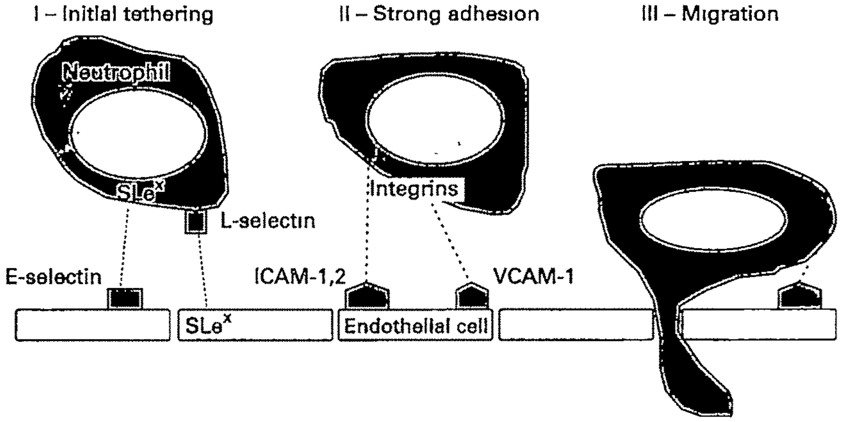

Figure 2 Stages of neutrophil adhesion to, and migration across, the endothelium.

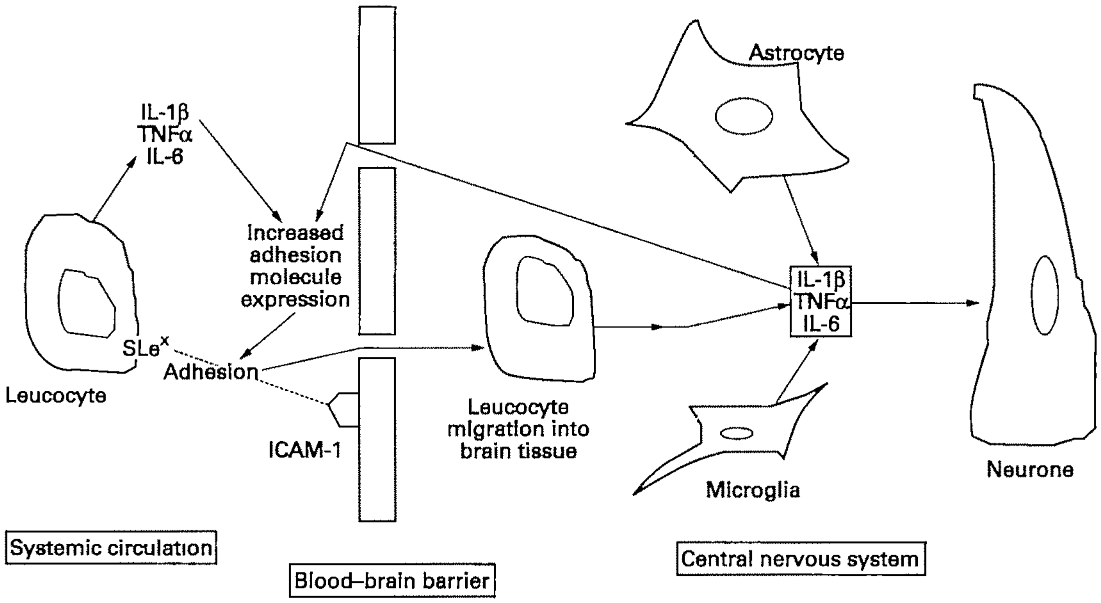

Figure 3 Intracranial cytokine and adhesion molecule interactions.

tion of the effects of these molecules may prove to be a powerful tool in the treatment of inflammatory disease. A review of the adhesion molecules by Froese and colleagues can provide additional background information.[51] The most extensively studied molecule is ICAM-1, a member of the immunoglobulin "superfamily". This molecule is expressed on the vascular endothelium and, as has already been stated, facilitates strong adhesion and migration of white cells from vessels into tissue. There is also evidence of its role in the intra-parenchymal binding of leucocytes to tissue cells such as astrocytes in the CNS.[92] The soluble forms of the adhesion molecules (e.g. sICAM-1) are those which can be measured by assay in the serum or plasma of normal individuals,[86] but the part they play in the physiological response to injury is unclear. Increased concentrations of the soluble endothelial molecules (sICAM-1, sE-selectin) may result from damage to the endothelium as a result of systemic inflammatory processes. Alternatively, these same processes may cause "activation" of the endothelium, with upregulation of production and shedding of these molecules into blood.[56] Investigators have explained changes in concentrations of the soluble form of L-selectin (one of the leucocyte bound molecules) in different ways,[23 99] which are discussed below.

Laboratory studies add weight to the evidence provided by the small number of clinical studies on this subject in brain injury. PMN accumulate in damaged brain tissue[32] and there is a significant correlation between the degree of PMN accumulation and the extent of cerebral oedema in rats.[87] There is little laboratory work on this subject in TBI; most studies have examined adhesion molecules in stroke models, although this work is certainly relevant to all forms of cerebral ischaemia. Wang and Feuerstein showed, in a rat stroke model, an increase in cortical E-selectin expression by 6 h after injury, which peaked at 12 h and returned to basal concentrations by day 5. ICAM-1 expression is also increased 3 h after injury and remains increased for 5 days.[106] Clark and colleagues studied CNS reperfusion injury in rats, with a temporary middle cerebral artery occlusion (MCAO) model. This important study showed an increase in cortical ICAM-1 expression from 1 h after injury. This correlated with moderate infiltration of PMN in the areas of ICAM-1 expression.[19] There is an upregulation of cortical E-selectin after cerebral reperfusion injury in primates,[39] and after SAH in rats there is increased expression of ICAM-1 on cerebrovascular endothelial cells.[38] Another recent study showed that ICAM-1 deficient mice were less susceptible to cerebral ischaemia/reperfusion injury.[97]

Many of the clinical studies on the subject of adhesion molecules carried out to date have been in the SIRS patient population. Cowley and co-workers found that serum concentrations of sICAM-1, sVCAM-1 and sE-selectin were increased in SIRS, particularly if there was multiple organ dysfunction (MOD).[23] A high sE-selectin concentration correlates closely with MOD and death.[23] Other studies also showed that sICAM-1[89] and sE-selectin[73] were increased in SIRS (concentrations of sICAM-1 were significantly higher after 24 h in non-survivors than survivors). Patients with multiple trauma have also been studied: an increase in serum sICAM-1 after multiple trauma correlated with the severity of subsequent MOD.[56]

There are only a small number of clinical studies which have investigated adhesion molecules in neurological disease and non-traumatic brain injury. ICAM-1 expression is increased in the cerebral vessels of patients with diagnoses of multiple sclerosis, viral encephalitis and cerebral infarct[96] and there is a high concentration of sICAM-1 in the CSF[42 80] and blood[42] of patients with bacterial meningitis, which correlates with measures of blood–brain barrier dysfunction.[80] Kim and colleagues studied leucocyte integrin expression in patients with a diagnosis of stroke or transient ischaemic attack and found increased expression of CD11a and CD18.[48] Lindsberg and co-workers studied brain sections of patients who had died from stroke disease and showed increased expression of endothelial ICAM-1.[59]

There are no published studies to date which have investigated serial changes in adhesion molecules in TBI or spontaneous SAH, but Keskil and colleagues reported that in a group of 153 patients with TBI there was a good correlation between injury grading and admission white cell count.[45] In a recent stroke study, Fassbender and colleagues found increased sICAM-1 and reduced sL-selectin concentrations in patients with significant risk factors for stroke, and in addition found increased sICAM-1, reduced sL-selectin, increased sE-selectin and sVCAM-1 concentrations in a group who had sustained a stroke.[29] This decrease in sL-selectin is explained by the notion that activated endothelial counter receptors "mop up" the "pool" of sL-selectin in serum. This theory supports the findings of Donnelly and colleagues.[25] They found reduced sL-selectin concentrations in the serum of a subgroup of patients who progressed to develop the acute respiratory distress syndrome from a sample judged to be "at risk" on recruitment to the study. Blann and colleagues proposed a similar theory to explain their findings of a reduced concentration of sL-selectin in patients with systemic sclerosis and vasculitis. They also showed an inverse relationship between serum sL-selectin concentration and disease severity.[10]

It is apparent therefore that acute brain injury causes increased expression of leucocyte adhesion molecules on cerebrovascular endothelium and in brain tissue itself, with expression mediated by cytokines. The final step in the investigative pathway is to examine the effects of cytokine and adhesion molecule antagonists on the process, and to examine if these compounds may potentially improve neurological outcome after brain injury.

Anti-cytokine and anti-adhesion molecule therapy

There are several questions to be answered in the final part of this review. What effects do anti-cytokine therapies have on cerebral tissues and expression of adhesion molecules after acute brain injury? Do monoclonal antibodies to adhesion molecules reduce secondary damage after a cerebral insult, and what effects do these potential therapies have in injuries to other organ systems? It is important, however, to consider that the cytokines function as natural communication molecules in host defence, and so antagonism of their actions may also have detrimental effects.

In experimental anti-cytokine therapy for brain injury, findings are encouraging. The increase in blood–brain barrier permeability and CSF white cell count caused by administration of intra-cisternal TNFα is abolished by treatment with a TNFα antibody.[55] Two studies examined the effects of anti-cytokine therapy on cerebral oedema: in a rat MCAO model, administration of an IL-1 blocker reduced cerebral oedema[110]; more recently, Shohami and co-workers showed that after TBI in the rat, administration of TNFα antibody caused a reduction in cerebral oedema and facilitated recovery of motor function.[93]

IL-1ra shows promise as a neuroprotective agent. Professor Nancy Rothwell's group in Manchester, provided what is probably the first direct evidence for cytokine involvement in brain injury when they showed that ischaemic and neurotoxic damage in the rat is inhibited by IL-1ra.[78] In a later study they gave IL-1ra to rats who had sustained a TBI. In the group where treatment was given immediately after injury, a reduction in lesion size, assessed histologically, of 44% was found. Even if treatment was delayed by 4 h, a 28% reduction in lesion size was seen.[103] Another approach to antagonizing the effects of IL-1β is to block the action of IL-1β converting enzyme (ICE), which converts the precursor molecule pro-IL-1β to its active form. Rothwell's group showed that administration of an ICE inhibitor reduced ischaemic brain damage in a rat model.[62]

Some workers have studied the effects of anti-cytokine therapy on adhesion molecule expression. In mice who have sustained a penetrating stab wound to the brain, treatment with antibody to IL-1 results in a significant reduction of ICAM-1 positive glia at 24 and 48 h after injury,[92] and cytokine specific antisera inhibit induction of ICAM-1 in adenocarcinoma cell lines by IL-1β and TNFα.[83] The evidence would therefore suggest that anti-cytokine therapy is indeed capable of reducing cerebral tissue damage and adhesion molecule expression after brain injury.

Finally, we should consider the therapeutic potential of blocking the actions of the adhesion molecules themselves. This will of course antagonize a natural body defence mechanism, and may in some cases be detrimental, but it is theoretically a more attractive option than attempting to block the diverse actions of the cytokines, with their complex inter-relationships. Clark and Zivin have recently published a detailed review on this subject in stroke disease,[22] but the subject has received little attention by investigators in TBI research.

Two groups have made substantial progress using models of CNS ischaemia. In 1991, Clark's group from Oregon published two articles[20 21] which examined the effects of anti-adhesion molecule antibodies in CNS ischaemia and showed that antibody to the integrin CD18 and to the immunoglobulin ICAM-1 produced a significant reduction in neurological deficits in a model of spinal cord ischaemia. This implicates leucocytes in CNS reperfusion injury. Zhang's group from Detroit has published findings from several studies in rat stroke models since 1994. They showed that antibody to various adhesion molecules reduces infarct size and PMN infiltrate.[16 43 112] In more recent work the group has looked at the effect of giving antibodies later than at the onset of ischaemia, which is much closer to the clinical situation. They showed that treatment with anti-integrin or anti-ICAM-1 antibodies several hours after the onset of ischaemia results in reduced infarct size.[17 113] Other groups have reported similar benefits.[58 66]

Other antagonists may have a part to play in future anti-adhesion therapy: heparin oligosaccharides bind to L- and P-selectin and thus inhibit their binding to other counter-receptors,[72] and inositol polyanions reduce binding of L- and P-selectin *in vitro*.[13]

This evidence suggests that administration of agents which antagonize the harmful effects of neutrophil adhesion and migration into tissue may reduce secondary brain injury in humans, although again we must be aware that adhesion and migration of leucocytes are natural responses of the host to injury, and that antagonism of these actions may reduce the positive effects of the inflammatory response. Phase three trials of an anti-ICAM-1 antibody are currently in progress in patients with stroke disease, and we await the results with great interest.

Conclusion

Research to date strongly implicates cytokines such as IL-1β, IL-6 and TNFα, together with the leucocyte adhesion molecules, in the pathophysiological response to primary brain injury. The cascades or webs of mediators released after primary injury cause secondary brain injury which may be severe. Prevention of systemic hypoxaemia, hypotension and hypothermia, together with optimization of oxygen delivery to the brain are priorities in the current intensive care management of acute brain injury.

Despite improvements in pre-hospital and intensive care, mortality and morbidity caused by traumatic brain injury has not decreased substantially in the past decade. Further work in the areas of anti-cytokine and, in particular, anti-adhesion molecule therapy may result in the clinical use of these novel therapies, which may alleviate the devastating secondary sequelae of an acute injury to the brain.

SHORT COMMUNICATIONS

Effect of dexamethasone on postoperative emesis and pain

K. Liu, C. C. Hsu and Y. Y. Chia

Summary

In this double-blind, randomized, placebo-controlled study, we have evaluated the effect of preoperative administration of dexamethasone on postoperative vomiting and pain in 60 women undergoing general anaesthesia for major gynaecological surgery. Dexamethasone 10 mg (group D) or saline (group S) was administered i.v. in a double-blind manner during induction of anaesthesia. Postoperative pain relief was controlled with bolus doses of morphine using an i.v. patient-controlled analgesia device, and patients were assessed for incidence of vomiting, sedation score, verbal pain rating score, time to first morphine demand and morphine consumption at 4, 8, 12 and 24 h after surgery. Six patients in group D and 19 in group S experienced vomiting at least once within the 24-h postoperative period; dexamethasone was effective in reducing the overall incidence of vomiting from 63.3% to 20.0% ($P < 0.01$). Other variables were similar between the groups, and the influence of dexamethasone on postoperative pain was minimal.(*Br. J. Anaesth.* 1998; **80**: 85–86)

Keywords. pharmacology, dexamethasone; vomiting, nausea, postoperative; vomiting, incidence; pain, postoperative; analgesia, patient-controlled

In 1964, Smith and colleagues injected a steroid–penicillin–local anaesthetic mixture into the tonsillar fossae during surgery and observed a reduction in postoperative pain and inflammation.[1] In 1972, Papangelou compared oral dexamethasone, in combination with analgesics, with analgesics alone, in 480 patients undergoing tonsillectomy and found less tissue oedema and pain in the steroid-treated group in the postoperative period.[2] After the antiemetic effect of dexamethasone had been well established in patients receiving cancer chemotherapy in the 1980s, McKenzie and co-workers showed that ondansetron and dexamethasone were more effective than ondansetron and saline in the prevention of postoperative nausea and vomiting (PONV).[3] Recently, the antiemetic effect of dexamethasone alone was demonstrated successfully in paediatric tonsillectomy patients and ambulatory gynaecological patients.[4 5] Tissue injury-induced acute inflammation is known to play a significant role in the genesis of surgical pain, and dexamethasone should theoretically be beneficial in the management of acute surgical pain because of its potent anti-inflammatory effect. In this study, we have examined a single dose of dexamethasone 10 mg i.v. as an antiemetic and its influence on postoperative pain in adult patients undergoing major gynaecological surgery.

Methods and results

After obtaining approval from the Human Investigation Committee and informed patient consent, we studied 60 ASA I–II patients undergoing major gynaecological procedures. Anaesthesia was induced with fentanyl 5 μg kg^{-1} and diazepam 0.15 mg kg^{-1}; tracheal intubation was facilitated with lidocaine 1.5 mg kg^{-1}, thiopental 4 mg kg^{-1} and succinylcholine 1.5 mg kg^{-1}. General anaesthesia was maintained with halothane or isoflurane, 50% nitrous oxide in oxygen and i.v. infusion of atracurium. Before surgical incision, dexamethasone 10 mg or normal saline 2 ml was administered i.v. in a double-blind manner. At the end of operation, the trachea was extubated when the train-of-four ratio was greater than 75% without the aid of an anticholinesterase.

For postoperative analgesia, a PCA pump was programmed to deliver morphine 1.5 mg i.v. on demand with a lockout interval of 10 min, and pain intensity was rated by patients using a 0–10 verbal pain score (VPRS 0–10: 0 = no pain, 10 = most severe pain imaginable). Level of sedation was assessed by staff in the acute pain team using a 0–3 scale (0 = fully awake; 1 = asleep with response to stimulus; 2 = asleep without response to stimulus; 3 = comatose). Episodes of vomiting, VPRS, sedation score, time to first morphine demand and morphine consumption were recorded at 4, 8, 12 and 24 h after operation. Duration of hospital stay was also noted. Rescue antiemetic administration of prochlorperazine 10 mg i.m. was given at the patient's request. Data were analysed using the Student *t* test, chi-square test or Mann–Whitney *U* test, as appropriate, and are presented as mean (SEM). Statistical significance was assumed at $P < 0.05$.

There was no significant difference between groups in age, weight, height, ASA status, type and duration of surgery, duration of hospital stay, VPRS, sedation score, time to first morphine demand or morphine consumption (table 1). Emesis occurred in six of 30 (20.0%) patients in group D compared with 19 of 30 (63.3%) in group S ($P = 0.00738$). Among those who experienced emesis, all six of group D and

Table 1 Postoperative morphine consumption (mg) (mean (SD))

Time after surgery (h)	Group D (n=30)	Group S (n=30)
4	3.1 (0.2)	3.4 (0.2)
8	5.6 (0.5)	6.5 (0.4)
12	8.1 (0.8)	9.5 (0.6)
24	14.4 (1.4)	16.9 (1.0)

Table 2 Number of patients who vomited. $^*P < 0.05$

Vomiting episodes	Group D (n=30)	Group S (n=30)	P
> 4	0	5*	0.02609
1-4	6	14*	0.02846
0	24	11*	0.00066
Incidence	20%	63.3%	
Patients received prochlorperazine	0	8*	0.00229

14 of group S patients had vomited no more than four times ($P = 0.02846$); the remaining five patients in group S vomited more than four times ($P = 0.02609$). The frequency of emesis in group S was significantly higher than that in group D (table 2).

Comment

The mechanism of dexamethasone-induced antiemesis is not fully understood, but central inhibition of prostaglandin synthesis[6] and decrease in 5-HT turnover in the central nervous system[7] or changes in the permeability of the blood CSF barrier to serum proteins[8] may be involved.[9] In contrast with the reported decreased wound pain following extraction of third molar teeth after dexamethasone administration,[9] the consistent reduction in morphine requirements observed in group D patients in this study was not significant ($P = 0.053$). Different postoperative pain intensities among these patients may be the major reason for this discrepancy. With its strong anti-inflammatory effect, dexamethasone should theoretically be beneficial for acute surgical pain, while for pain of lesser extent, its influence should be evident; for worse pain, its influence tends to be relatively small.

The number of patients required for this study was calculated to detect a difference in morphine requirements of 1.1 mg with a power of 90% at the 5% level of significance. Based on this, a minimum of 22 patients was required in each group. There were 30 patients in each group which implies that comparisons between groups were effective.

Dexamethasone is known to cause side effects such as increased incidence and severity of infection, adrenal suppression and delayed healing in surgical patients. The lack of difference in duration of hospital stay between groups implied that there was no additional wound infection or delayed healing accompanying dexamethasone usage. However, detailed investigation with a longer follow-up would be necessary to investigate this. The reported dose of dexamethasone for prevention of PONV is 0.15 mg kg^{-1}, up to a maximum of 10 mg i.v., yet favourable results were also noted with a single oral dose of dexamethasone 8 mg in adult patients.[9]

Among the antiemetics currently used, 5-HT antagonists (ondansetron, granisetron) are known to possess good antiemetic efficacy; however, their cost limits widespread clinical use. As emesis is not caused by a single mechanism at a specific site, studies with various combinations of antiemetics with different mechanisms of action may be promising. Dexamethasone, its with significant antiemetic properties and no evident adverse effects, may be a valuable constituent of combination antiemetic therapy.

Changes in hepatocellular integrity during and after desflurane or isoflurane anaesthesia in patients undergoing breast surgery

P. TIAINEN, L. LINDGREN AND P. H. ROSENBERG

Summary

We have assessed hepatocellular integrity in patients anaesthetized with desflurane or isoflurane using glutathione transferase Alpha (GSTA) as a sensitive indicator. Volatile anaesthetic was administered to 72 women at 0.7 MAC for 25 min and thereafter at 1.0 MAC. GSTA was measured with a time-resolved immunofluorometric assay in serum samples. Mild or moderate increases in GSTA were found in approximately 40% of patients immediately after anaesthesia. In the desflurane group ($n = 30$) the increase in GSTA concentration was from a baseline value of the geometric mean of 1.3 μg litre^{-1} (95% confidence interval 0.9–1.9 μg litre^{-1}) to a peak of 2.6 (1.8–3.8) μg litre^{-1}. The corresponding increase in the isoflurane group ($n = 31$) was from 1.3 (0.9–1.9) μg litre^{-1} to 3.0 (2.2–4.2) μg litre^{-1}. The change in GSTA concentration was significant in both groups but not between groups. No predictive factors for the increase in GSTA concentrations were found. Increased GSTA concentrations were not accompanied by increases in aminotransferases. We conclude that desflurane and isoflurane anaesthesia were associated with a mild subclinical disturbance of hepatocellular integrity. (*Br. J. Anaesth.* 1998; **80**: 87–89)

Keywords: anaesthetics volatile, desflurane; anaesthetics volatile, isoflurane, enzymes, glutathione S-transferase; liver, function

We have found a mild disturbance in hepatocellular integrity during halothane,[1 2] sevoflurane,[1] isoflurane[2] and propofol anaesthesia[3] by measuring glutathione transferase Alpha (GSTA) in serum.[4] GSTA is a sensitive and rapidly reacting indicator of hepatocellular integrity.

Desflurane anaesthesia has generally not been associated with deleterious effects on the liver. Liver blood flow is well maintained during desflurane anaesthesia,[5 6] and its metabolism is minimal. Only one case of severe liver injury has been reported after desflurane anaesthesia[7] and it may be superior to other inhalation anaesthetics in this regard. Therefore, we measured serum GSTA concentrations after desflurane and isoflurane anaesthesia.

Methods and results

The study was approved by the local Ethics Committee and each patient gave written informed consent. Seventy-two women (aged 25–60 yr, ASA I–II) undergoing breast surgery were allocated randomly to receive either desflurane or isoflurane anaesthesia. Exclusion criteria, premedication, induction of anaesthesia, positive pressure ventilation, additional drugs, monitoring, postoperative observation and pain treatment were similar to the conditions in our previous study.[2] Desflurane or isoflurane were administered at 0.7 MAC (adjusted for age) for 25 min and thereafter at 1.0 MAC until the end of anaesthesia. At least 800 ml of Ringer's acetate solution were infused during anaesthesia according to blood loss and haemodynamics. Hydroxyethyl starch was infused when blood loss exceeded 400 ml. Relative hypotension was defined as a mean arterial pressure of less than 65% of baseline for more than 15 min and absolute hypotension as a mean arterial pressure of less than 60 mm Hg for more than 15 min. Decrease in arterial pressure was treated with i.v. fluids and temporary decrease of volatile anaesthetic to 0.8 MAC. Heart rate was classified as bradycardia (less than 60 beat min^{-1} for more than 40% of the duration of anaesthesia), normal (60–80 beat min^{-1} for more than 60% of the duration of anaesthesia) or tachycardia (more than 80 beat min^{-1} for more than 40% of the duration of anaesthesia).

Serum samples were collected before anaesthesia (baseline) and at 0, 1, 2, 4, 8, 20 and 44 h after the end of anaesthesia. GSTA was measured by a time-resolved immunofluorometric assay,[4] as described in our previous study.[2] Aminotransferases, glutamyl transferase and bilirubin were assayed in baseline samples. Aminotransferases were also measured 20 and 44 h after anaesthesia.

The assumptions for a power analysis were that a difference of 0.22 on log(10) scale (i.e. 40% under or 66% over the isoflurane group) is "clinically significant", that the SD is 0.3 on log(10) scale, and that 15% of patients have baseline GSTA concentrations more than 6.0 μg litre^{-1} and such patients are excluded. A power of 80% at $\alpha = 0.05$ required 36 patients in both groups.[8] Individual GSTA results were compared using repeated measures analysis of

variance (ANOVA) techniques, as described previously.[2] The area under the curve (AUC) values for GSTA were measured by calculating the positive area over baseline from induction to 8 h after the end of anaesthesia. Peak and AUC values of GSTA were compared between groups using the *t* test. AUC values of GSTA were classified as low (<5 μg h litre^{-1}) and increased (≥5 μg h litre^{-1}) for log-linear analysis with arterial pressure, heart rate, blood loss (<500 ml *vs* ≥500 ml), administration of hydroxyethyl starch, addition of nitrous oxide, duration of anaesthesia (<180 min *vs* ≥180 min), age (<47 yr *vs* ≥47 yr) and body mass index (<24 kg m^{-2} *vs* ≥24 kg m^{-2}). The log-linear models were tested on two-way (each variable above and AUC) and three-way (volatile anaesthetic, each variable above and AUC) tables. Systat software was used for computing. Statistical significance was defined as $P < 0.05$.

The results of 61 patients were analysed. Reasons for exclusion were increased baseline GSTA in 10 patients and lost samples in one case. One patient underwent reoperation because of bleeding 5 h after the end of anaesthesia and her laboratory data 4, 8, 20 and 44 h after the initial anaesthesia were not included. The groups were comparable in patient and anaesthetic characteristics, fluid management, bleeding and haemodynamic data (table 1).

Changes in GSTA concentrations (table 2) were significant (repeated measures ANOVA) in the desflurane (P = 0.001) and isoflurane (P = 0.02) groups, but not between groups. Neither peak nor AUC values of GSTA differed between groups. Peak GSTA concentrations were greater than the reference range (0.7–6.0 μg litre^{-1}) in six patients in the desflurane group and in eight patients in the isoflurane group. Seven patients in the desflurane group and 10 in the isoflurane group had AUC values of 5–20 μg h litre^{-1}. AUC values of more than 20 μg h litre^{-1} were demonstrated in four and five patients, in the desflurane and isoflurane groups, respectively.

Three patients in the desflurane group and five patients in the isoflurane group exhibited a secondary peak of more than 3 μg litre^{-1} above baseline at 20 or 44 h after anaesthesia. One patient in the desflurane group, who underwent reoperation because of postoperative bleeding, exhibited a secondary peak of 101 μg litre^{-1} 8 h after the initial anaesthesia. Alanine aminotransferase concentrations also increased to 372 iu litre^{-1} and aspartate aminotransferase to 384 iu litre^{-1} 20 h after anaesthesia in this patient.

There was no significant association between the following variables and increased GSTA concentrations (log-linear model on two-way table) or between volatile anaesthetic, the following variables and increased GSTA (log-linear model on three-way tables): hypotension (P = 0.20 (two-way), P = 0.11 (three-way)), relative hypotension (P = 0.47, P = 0.37), absolute hypotension (P = 0.10, P = 0.30), bradycardia (P = 0.34, P = 0.38), hypotension and bradycardia (P = 0.27, P = 0.49), blood loss (P = 0.47, P = 0.52), administration of hydroxyethyl starch (P = 0.19, P = 0.51), addition of nitrous oxide (P = 0.42, P = 0.67), duration of anaesthesia (P = 0.38, P = 0.41), age (P = 0.63, P = 0.21) or body mass index (P = 0.92, P = 0.56). There was a minimal decrease in aminotransferase activities after anaesthesia.

Comment

We found a temporary increase in GSTA that was similar in both desflurane and isoflurane groups and comparable with our earlier studies.[1–3] The mechanisms of mild disturbance in hepatocellular integrity during or immediately after anaesthesia are still unclear. General haemodynamic depression is probably not the explanation for GSTA release because hypotension or bradycardia were not associated with increased GSTA concentrations. Local haemodynamic differences could be involved but hepatic blood flow is better maintained and autoregulation is probably more intact during isoflurane or desflurane anaesthesia than during halothane anaesthesia.[5 6] The possible influence of surgery on hepatocellular integrity cannot be excluded, but all operations in the present and two previous studies[2 3] were performed at superficial sites. Positive pressure ventilation may disturb hepatocellular integrity as has been demonstrated during halothane and isoflurane anaesthesia.[9] It is doubtful if this is a universal finding as an increase in GSTA has been found after sevoflurane anaesthesia with positive pressure ventilation[1] and with spontaneous ventilation.[10]

Eight patients exhibited a similar secondary increase in GSTA, as seen in previous studies.[1 2] However, only the patient whose peak GSTA concentration was 101 μg litre^{-1} after hypovolaemia and reoperation was shown to have developed more advanced, transient liver injury, as indicated by increased activities of aminotransferases. Peak concentrations of GSTA in this patient would probably have been considerably higher than those observed if blood samples had been collected more frequently during and after reoperation. The short half-life of GSTA in serum is a great advantage for demonstration of active liver injury. On the other hand, it is also a major limitation because it is impossible to estimate the peak or AUC values of GSTA if sampling is delayed.

The mild disturbance in hepatocellular integrity that appeared in the present and previous studies[1–3] seems to be unpredictable and without any clinical significance in most cases. However, it might have some clinical significance in the patient who underwent reoperation in this study and in two patients whose GSTA peaks were more than 300 μg litre^{-1} after halothane anaesthesia in the previous study.[2] Mild or moderate increases in GSTA (peak less than 50 μg litre^{-1}) commonly occur immediately after general anaesthesia without any clear difference between anaesthetics. These small changes are transient and not associated with clinical liver pathology.

We conclude that desflurane anaesthesia was accompanied by a minor increase in GSTA concentration of the same magnitude as that after isoflurane anaesthesia and has no clinical significance.

Acknowledgements

We are grateful to Associate Professor Kimmo K. Karhi, PhD, Division of Biochemistry, Department of Biosciences, University of Helsinki, for laboratory facilities for GSTA assays. We thank Mr Oula Penate Medina, BSc, for technical help in GSTA assays. Pharmacia-Upjohn supported this study by providing a desflurane vaporizer and an equipment accessory to Capnomac Ultima for desflurane analysis.

5-Hydroxytryptamine causes depression of twitch height in the partially curarized rat phrenic nerve hemidiaphragm preparation

A. T. HINDLE AND P. M. HOPKINS

Summary

5-Hydroxytryptamine (5-HT) has significant effects on the skeletal neuromuscular junction. We have evaluated the potential neuromodulatory effects of 5-HT on the rat hemidiaphragm using a non-fatiguing pattern of stimulation (0.3 Hz) in a partially curarized preparation using tubocurarine (EC_{50} = 560 (range 400–650) nmol litre^{-1}). 5-HT was added to the partially curarized preparation in the following concentrations: 0, 12.5, 25, 50, 100, 200 and 400 nmol litre^{-1} and the twitch response was recorded at each concentration. These measurements were expressed as a ratio of control values, plotted against time and the area under the curve (AUC) calculated. The AUC values for test and control hemidiaphragms were compared by paired *t* test analysis accepting a 5% significance level. The mean AUC for test (3327 mm^2) and control (4102 mm^2) preparations were significantly different ($P = 0.003$). We have shown that the addition of low concentrations of 5-HT to the indirectly stimulated partially curarized rat diaphragm preparation caused depression of twitch height. (*Br. J. Anaesth.* 1998; **80**: 90–91)

Keywords: serotonin (5-hydroxytryptamine); neuromuscular block, measurement of response; neuromuscular block, tubocurarine; rat

5-Hydroxytryptamine (5-HT) is released from the nerves innervating skeletal muscle preparations[1] where it may modulate the action of acetylcholine. High concentrations of 5-HT (millimolar) exhibit depressant effects on single twitch responses of skeletal muscle preparations.[2 3] Previous workers have suggested that the reduction in twitch height produced by 5-HT may be a result of a curare-like effect on the motor end-plate of skeletal muscle[4] but have failed to demonstrate that 5-HT exhibits a curare effect on skeletal muscle at resting rates of stimulation.[5] When 5-HT is applied at bath concentrations in excess of 5 mmol litre^{-1}, necrotic effects have been observed in *in vitro* skeletal muscle preparations.[6] In order to examine the interactions of 5-HT with neuromuscular blocking agents we tested the following null hypothesis: 5-HT has no effect on twitch responses of the vertebrate skeletal muscle where the safety factor for transmission at the neuromuscular junction has been reduced by application of tubocurarine. We investigated the effects of 5-HT added cumulatively (0–400 nmol litre^{-1}) to a partially curarized rat phrenic nerve diaphragm preparation.

Methods and results

Male Wistar rats (200–300 g) were used as a source of phrenic nerve diaphragms. The diaphragms were dissected out after the animals were killed by stunning and decapitation. Excess tissue was removed from the dissected diaphragms which were placed subsequently in a tissue bath containing oxygenated (95% oxygen–5% carbon dioxide) Krebs solution maintained at 37 °C. The diaphragms were pre-tensioned to 4 g and stimulated indirectly at supramaximal voltage (4–12 V). A Digitimer DS9A stimulator was set to deliver electrical stimuli with a pulse width of 0.5 ms and frequency of 0.3 Hz. No licence was needed as animals were killed under schedule 1 of the Animals (Scientific Procedures) Act 1986.

Responses were recorded isometrically, transduced (Ormed 4157) and displayed on a Windograf recorder (Gould Instruments). The recording apparatus was calibrated at the start of each experiment. This was carried out by suspending pieces of metal of known weight (0.5 g, 1 g) from the arm of the transducer and recording the deflection on the Windograf display up to a total of 4 g deflection.

Tubocurarine was added cumulatively in 200-nmol litre^{-1} increments and twitch height was allowed to stabilize between addition of one concentration and the next. This was continued until all twitches were abolished. The excitatory concentration which produced 50% (EC_{50}) depression of twitch height was calculated. The hemidiaphragms were exposed to a standardized wash cycle and allowed to equilibrate for 30 min. The EC_{50} dose of tubocurarine was added to the preparation and the twitch response allowed to stabilize.

5-HT (Ciba Geigy) was added cumulatively to one hemidiaphragm preparation in the following concentrations: 12.5, 25, 50, 100, 200 and 400 nmol litre^{-1}, while an equal volume of control solution (Krebs) was added to the contralateral diaphragm which acted as a time-matched concurrent control. Five minutes were allowed between successive additions of each concentration of 5-HT.

P. M. HOPKINS, MD, FRCA, Academic Unit of Anaesthesia, St James's University Hospital, Clinical Sciences Building, Beckett St, Leeds LS9 7TF. A. T. HINDLE, BSC (HONS), FRCA, Health Care International Medical Centre, Beardmore St, Clydebank G81 4HX. Accepted for publication: August 25, 1997.

Correspondence to A. T. H.

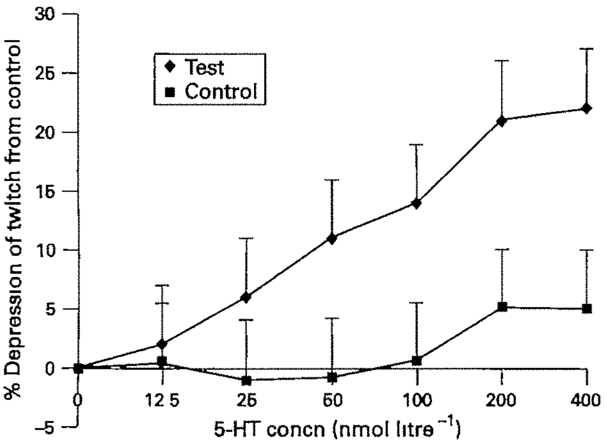

Figure 1 Effects of 5-HT on the partially curarized diaphragm. The X axis refers to the concentration of 5-HT, each individual concentration being added cumulatively. The Y axis refers to the percentage depression of twitch height from baseline. In this instance "baseline" refers to the twitch height of the partially curarized preparation before addition of 5-HT. Data are mean (SEM).

The twitch response of the hemidiaphragm after addition of tubocurarine acted as the reference value against which all other twitch responses, after addition of 5-HT or control, would be compared. Twitch height after addition of each concentration of 5-HT was recorded and expressed as a ratio over the reference value. The recordings from the contralateral diaphragm (time-matched concurrent control) were treated in the same way. The ratios were plotted subsequently against time for each experiment. The area under the curve (AUC) of the time ratio response relationship was calculated and the values of the areas for test and control preparations were compared by paired *t* test analysis accepting a 5% level of significance. For presentation purposes the data have been presented in the form of a concentration–response relationship.

There was consistent depression in twitch height in the preparation treated with 5-HT compared with controls ($n = 7$). A plot of change in twitch response over time indicated that the mean areas were significantly different between treatment and control groups ($P = 0.003$). The results for the seven pairs of experiments are summarized in figure 1.

Comment

In this study we have demonstrated that 5-HT depressed the twitch response in a partially curarized preparation when added at low concentrations (12.5–400 nmol litre^{-1}) but had no effect in the absence of tubocurarine at the same concentrations. This would imply that the presence of tubocurarine compromised the interaction of acetylcholine with its receptors at the neuromuscular junction in such a way that 5-HT was able to evoke a depressant effect on the indirect twitch response of skeletal muscle. This could imply that 5-HT was either depressing the release of acetylcholine from the presynaptic terminal or reducing postsynaptic sensitivity to the effects of acetylcholine. To the best of our knowledge this has not been demonstrated previously. However, previous studies carried out by us have shown that 5-HT can modulate the twitch responses of the indirectly stimulated rat diaphragm during tetanic stimulation.[7] In this situation it is possible that 5-HT is able to modulate twitch responses when the processes involved in acetylcholine replenishment are maximized.

We feel that these observations need further examination using a range of selective 5-HT agonists and antagonists in order to identify the receptor or receptors involved in the action of 5-HT. Further investigation is also required to help formulate a basis for possible interactions with other drugs already known to be active at the neuromuscular junction.

CASE REPORT

Use of methadone in the morphine-tolerant burned paediatric patient

P. I. WILLIAMS, R. E. SARGINSON AND J. M. RATCLIFFE

Summary

We describe the successful use of methadone in the restoration of sedation and provision of analgesia in two morphine-tolerant, paediatric patients who had suffered significant thermal injuries and were undergoing mechanical ventilation. Both patients had exhibited escalating requirements for sedative drugs while undergoing ventilation yet remained inadequately sedated. The introduction of i.v. methadone in place of i.v. morphine in the sedative regimen rapidly and effectively restored a state of sedation. Hyperalgesia and morphine tolerance appear to be associated; it is proposed that methadone acts primarily, under these circumstances, by re-establishing the analgesic state. Such use of methadone in the morphine-tolerant patient also afforded a concomitant sedative-sparing effect. (*Br. J. Anaesth.* 1998; **80**: 92–95)

Keywords: analgesia, paediatric; sedation; intensive care, sedation; analgesics opioid, methadone

Case report

PATIENT NO. 1

An 18-month-old female, weighing 12 kg, was admitted to the regional paediatric intensive care unit (PICU) with 70% cutaneous burns of both partial and full thickness involving the face, neck, trunk and limbs. Additionally, there were airway burns and smoke inhalation injury. Tracheal intubation had been undertaken and intermittent positive pressure ventilation (IPPV) commenced before admission to the PICU; mechanical ventilation was continued throughout her admission. She underwent several surgical procedures of varying complexity for her burns. However, it became evident that survival would be most unlikely because of the severity of her initial injury and subsequent failure of skin engraftment. The child died on day 62. Throughout her stay in the PICU, her requirements for sedative drugs increased, gradually at first and then in a dramatic manner. The sedative regimen used, and the necessary changes made to it, are presented in table 1.

On day 49, at the time of stopping the i.v. morphine infusion, blood sampling was performed for assay of concentrations of morphine, morphine-3-glucuronide and morphine-6-glucuronide. The respective concentrations were subsequently reported as follows: morphine 202 nmol litre^{-1}, morphine-3-glucuronide 1308 nmol litre^{-1} and morphine-6-glucuronide 527 nmol litre^{-1}.

Table 1 Patient No. 1: sedative regimen used and necessary changes to this regimen

Day	Sedative requirements
Admission	I.v. infusions of midazolam 80 μg kg^{-1} h^{-1} and morphine 40 μg kg^{-1} h^{-1} instituted with i.v boluses of vecuronium 1 mg as required to ensure compliance with mechanical ventilation
11	With midazolam and morphine being infused i v. at doses of 100 μg kg^{-1} h^{-1} and 60 μg kg^{-1} h^{-1} respectively, promethazine 12 mg via the nasogastric (n.g.) route at regular 6-h intervals (qds) was added as a sedative adjunct
13	N.g. chloral hydrate 600 mg qds, was introduced to the existing regimen to ensure acceptable sedation
28	The sedative regimen now comprised i.v. midazolam 750 μg kg^{-1} h^{-1}, i.v. morphine 480 μg kg^{-1} h^{-1}, n.g promethazine 12 mg qds, and n.g. chloral hydrate 600 mg qds
35	Secobarbital was added at a dose of 50 mg twice daily (bd) via the n.g. route
38	It became necessary to add ketamine via i.v. infusion, the starting dose being 90 mg h^{-1}
39	I.v. ketamine was reduced to 35 mg h^{-1}
49	The sedative regimen comprised i.v. midazolam 2 mg kg^{-1} h^{-1}, i.v. morphine 390 μg kg^{-1} h^{-1}, i.v. ketamine 35 mg h^{-1}, n.g. promethazine 12 mg qds, n.g. chloral hydrate 600 mg qds and n.g secobarbital 50 mg bd. However, the child was restless, repeatedly attempting to remove her nasotracheal and nasogastric tubes, and non-compliant with a synchronized intermittent mandatory ventilation mode Additional bolus doses of midazolam 5 mg afforded only transient tranquillity. It was decided to substitute methadone for morphine. Morphine was stopped and an i.v. loading dose of methadone 2.75 mg kg^{-1} was administered over a period of 60 min, followed by an i.v. infusion of methadone 325 μg kg^{-1} h^{-1} which was maintained for the next 24 h. Simultaneously, i.v midazolam was reduced to 1.4 mg kg^{-1} h^{-1} and i.v ketamine to 25 mg h^{-1}
50	The methadone dosage was then rationalized to 20 mg i v. thrice daily (tds), with each dose being administered over a 10-min period
53	Both ketamine and secobarbital were stopped and methadone reduced to 20 mg i.v. bd.
55	Effective sedation was provided by i.v. midazolam 830 μg kg^{-1} h^{-1}, methadone 20 mg i.v. bd and chloral hydrate 600 mg n g qds. Promethazine 12 mg n g qds was continued empirically for its antipruritic effect

PATIENT NO. 2

A 6-yr 2-month-old female, weighing 20 kg, was admitted to the regional PICU with 48% full thickness burns involving the trunk, waist, thighs and arms. Tracheal intubation had been undertaken and IPPV commenced before admission to the PICU; mechanical ventilation was continued. Subsequently, several surgical procedures were undertaken for her burn injuries. During her stay in the PICU, her sedative requirements escalated. The sedative regimen used, and the changes made to it, are presented in table 2.

Correspondence to P. I. W.

Table 2 Patient No. 2: sedative regimen used and necessary changes to this regimen

Day	Sedative requirements
Admission	I.v. infusions of midazolam 32 $\mu g\ kg^{-1}\ h^{-1}$ and morphine 20 $\mu g\ kg^{-1}\ h^{-1}$ commenced producing satisfactory sedation
5	The sedative regimen now comprised i.v. midazolam 200 $\mu g\ kg^{-1}\ h^{-1}$ and i.v. morphine 200 $\mu g\ kg^{-1}\ h^{-1}$
7	N.g. promethazine 12 mg qds and n.g. chloral hydrate 500 mg qds were added. I.v. midazolam was being infused at 500 $\mu g\ kg^{-1}\ h^{-1}$ with i.v. morphine at 160 $\mu g\ kg^{-1}\ h^{-1}$
10	The dose of i.v. morphine had been increased to 320 $\mu g\ kg^{-1}\ h^{-1}$ yet sedation remained inadequate. Therefore, it was decided to introduce methadone in place of morphine. The initial dose of methadone was 5 mg i.v. bd, the dose being administered over a period of 10 min
14	It was necessary to increase the dose of methadone to 5 mg i.v. tds
16	Increasing the daily dosage of methadone permitted a reduction in the dose of i.v. midazolam to 100 $\mu g\ kg^{-1}\ h^{-1}$
17	Weaning from mechanical ventilation was commenced. Midazolam was withdrawn, the dose of methadone reduced to 4 mg i.v. tds, and both promethazine and choral hydrate maintained at 12 mg n.g. qds, and 500 mg n.g. qds, respectively. Acceptable sedation was afforded by these doses
26	A further skin engraftment procedure led to the dose of methadone being restored to 5 mg i.v. tds
27	Mild agitation was apparent which responded readily to increasing chloral hydrate to 1 g n.g. qds
29	The trachea was extubated and the dose of methadone was switched from 5 mg i.v. tds to 8 mg n.g. tds; simultaneously, the dose of chloral hydrate was reduced to 500 mg n.g. qds and promethazine stopped. Spontaneous ventilatory function was deemed satisfactory
36	The patient was discharged from the PICU to a high-dependency bed on the paediatric burns ward. She was awake and free from pain, being maintained on methadone 6 mg orally tds and chloral hydrate 500 mg orally at night

Discussion

The most commonly identified goals of sedation in the paediatric intensive care unit are reduced patient distress, fewer unplanned extubations and facilitation of mechanical ventilation.[1] Optimal sedation of paediatric patients is considered difficult despite the use of frequent doses of many sedative agents.[1] Midazolam infusion has been shown to be an effective component in the sedation of the paediatric patient.[2–4] A significant disadvantage of the use of midazolam is the development of acute tolerance,[3] and it has been shown that there is increased clearance during continuous infusion.[4] Opioids are used for both their sedative and analgesic effects. It is well recognized that prolonged or frequent use of opioids is associated with the phenomenon of tolerance. Nevertheless, tolerance to opioids remains largely unexplained despite extensive interest in the underlying mechanism. Some factors are, however, evident; receptor occupancy is necessary for the development of tolerance,[5] both the mu and kappa receptors are affected,[6 7] continuous infusion of opioids produces more rapid tolerance than intermittent administration[8] and morphine tolerance develops without concurrent receptor downregulation.[9]Recent evidence suggests that mechanisms common to other forms of neuronal plasticity may mediate morphine tolerance.[10] Spinal cord *N*-methyl-D-aspartate receptor activation,[11–12] subsequent protein kinase C translocation and activation,[13] and nitric oxide synthesis[12] may be involved. Additionally, altered metabolism of morphine leading to an increased ratio of morphine-3-glucuronide to morphine-6-glucuronide has been associated with uncontrolled nociceptive pain.[14] Interestingly, there appears to be significant similarities between the mechanisms of hyperalgesia and morphine tolerance.[10]

In our patients with established morphine tolerance, with increasing doses of midazolam and additional sedative adjuvants being necessary, it was proposed that another opioid be given in place of morphine. Methadone was chosen for several reasons; it had been reported previously to be an effective analgesic in opioid-tolerant patients,[15–18] it had been used successfully in treating iatrogenic opioid dependency in PICU patients,[19] it is known to be an effective analgesic after paediatric surgery[20] and it produces more prolonged respiratory depression in children than morphine.[21]

In both patients, initial methadone administration produced rapid control of sedation. In patient No. 1, the need for sedative polypharmacy was reduced significantly and adequate sedation and analgesia were maintained at a considerably lower dose-equivalent with respect to morphine. An i.v. loading dose followed by i.v. infusion at the rate described did not produce haemodynamic instability. At discontinuation of the i.v. infusion, a thrice daily i.v. regimen was introduced. With the reduction in dosage of, or withdrawal of, other sedative agents, the daily dose of methadone administered was conservatively reduced. In patient No. 2, methadone was introduced as an initial twice daily bolus regimen on ceasing the i.v. infusion of morphine. Again, there was a considerably lowered dose-equivalent with respect to morphine. After tracheal extubation, methadone administration was changed from the i.v. to the enteral route. The existing daily dose of methadone was increased for two reasons: first, because of the simultaneous reduction in the daily dose of chloral hydrate and second, to make allowance for the fact that the oral bioavailability of methadone is reported to be 81%.[22] In both patients, the relatively long duration of action of methadone permitted twice or thrice daily dosing schedules.

Why can methadone be used successfully in the morphine-tolerant patient?

There is little doubt that there is incomplete cross-tolerance between morphine and methadone in animal models[23 24] and in the human population.[16 17] In the animal model, selective tolerance can be induced by selective agonists for all opioid receptor subtypes without any cross-tolerance occurring between the different receptor subtypes.[25] Methadone is a racemic mixture of laevorotatory (R–) and dextrorotatory (S–) isomers, with the analgesic activity of the racemate being a result almost entirely of the content of the R–isomer.[26] There is stereospecific binding of methadone at the mu-1, mu-2 and delta receptors, with R–methadone having approximately 10-fold higher affinity than S–methadone.[26] Compared with morphine, R–methadone has approximately the same affinity for the mu-1, mu-2 and delta receptors, but has significantly lower affinity than morphine for the kappa receptor. However, methadone has higher intrinsic activity than morphine at the mu receptor.[27]

In animal experiments, it has been demonstrated that the intrinsic activity of opioid agonists is inversely related to the degree of tolerance after continuous infusion.[28] Further work has shown that after establishing morphine tolerance, the potency of morphine is diminished whereas that of methadone is unaffected.[29] Thus the higher intrinsic activity of methadone compared with that of morphine is likely to be a key factor in incomplete opioid cross-tolerance.

Methadone has a chemical structure unrelated to that of morphine; methadone is a diphenylpropylamine whereas morphine is a phenanthrene. As a consequence of its structure, methadone inhibits 5-hydroxytryptamine (5-HT) and norepinephrine uptake whereas morphine does not, and it has been proposed that activity at the mu receptor and inhibition of both 5-HT and norepinephrine uptake combine to enhance the analgesic activity of compounds possessing these properties.[30]

Morphine is metabolized to morphine-3-glucuronide and morphine-6-glucuronide; there is evidence that abnormal accumulation of M-3-G is associated with an antinociceptive effect.[15 31] The metabolites of methadone are pharmacologically inactive.[32] It must be noted that at discontinuation of i.v. morphine infusion in patient No. 1, the ratios of M-3-G to M-6-G and morphine were within the usual ratios compared with previously published paediatric pharmacokinetic data.[33]

In opioid receptor pharmacology, it is considered that the kappa receptor mediates the inherent sedative properties of the opioid group of drugs.[34] It has been noted previously that morphine has a significantly greater affinity for the kappa receptor than either methadone isomer,[26] thus methadone has a markedly lesser inherent sedative action than morphine. Nevertheless, it has been reported that, in animal models where morphine tolerance has been induced, there is substantial tolerance to the pure kappa agonist U-50,488H[6]; thus both mu and kappa receptor activities are altered in morphine tolerance. It is possible that methadone could restore agonist activity at the kappa receptor in morphine tolerance but it must be remembered that methadone has a low affinity for this receptor and any clinical effect under such circumstances is likely to be of little significance.

It appears that, under the circumstances of this case report, it was the restoration of analgesia with methadone that was the essential component of success in restoring sedation in morphine-tolerant patients. This correlates well with the postulate that hyperalgesia and morphine tolerance are associated.

When substituting methadone for morphine in the morphine-tolerant patient, the estimated dose of methadone to be administered must be made cautiously and on an individual basis.[16] For the two patients described, and in previously reported paediatric oncology patients with morphine tolerance,[16 17] it is noteworthy that after introduction of methadone, analgesia was maintained with significantly lower doses compared with those of morphine at the time of its termination.

HISTORICAL ARTICLE

Anaesthesia in the 1920s

P. M. E. DRURY

Numbers and status of anaesthetists

At the time of publication of the first issue of the *British Journal of Anaesthesia* in July 1923, there were not many whole-time anaesthetists in this country, and these were confined to university teaching hospitals. Blomfield (1922)[5] stated that there were 27 specialists at 12 teaching hospitals in London, and a similar situation existed in the provinces. In the peripheral hospitals, anaesthesia was administered by general practitioners with part-time contracts and a special interest in the subject.[42] But in many cases, emergencies devolved to house officers with very little experience. Woolmer, the first Professor of the Faculty of Anaesthetists, has described his first administration of an anaesthetic (open drop chloroform) in an x-ray department in the dark, given within 1 h of arriving to take up a new appointment.[75] Any medical practitioner was considered competent to give an anaesthetic on qualification, a situation which concerned Buxton.[9] The General Medical Council had required, since 1911, that every doctor, on qualification, should provide evidence of instruction in anaesthesia, but Buxton felt that only the minimum was being done to comply with this requirement. Undoubtedly, many anaesthetics were given by an occasional administrator in a domestic setting or in a surgery. General anaesthesia was also required in the dental chair and many anaesthetics were given by dentists. The Dentists Act of 1921 admitted a few hundred experienced but unqualified people to the Dental Register.

A particular feature of the history of anaesthesia in this country is that, since its earliest days it has been largely in the hands of the medical profession, a fact admired by colleagues in the USA and Europe.[57] In many parts of the USA it was considered to be a nurse's job. No doubt in places the service was excellent but in the 1920s the situation was evolving and, on both sides of the Atlantic, extremely able doctors were emerging who considered anaesthesia to be worthy of a physician's full time attention. This process was postponed in Europe, where surgeons continued to dominate the management of anaesthesia by employing junior assistants, and making widespread use of local and regional techniques.

One reason why specialist anaesthetists were not a common feature was financial. At teaching hospitals, a small payment was usually made in recognition of duties towards undergraduates,[5] but the tradition was that services were given free in return for the opportunity of private practice through contact with surgeons. The anaesthetist, however, did not submit an account, but had to rely on the discretion of the surgeon for payment, generally a small fraction of his fee.[32] Unless there were other sources of income, this could have led to some financial difficulties, and in one case may have been a factor in a suicide.

The perception of today's anaesthetist by patients is not well defined, and it was probably even less so 75 yr ago. On one occasion the public may have been more aware of the anaesthetist's role; in December 1928, King George V had a rib resected for empyema complicating lobar pneumonia.[19] The anaesthetist was Francis Shipway of Guy's Hospital, and when honours were distributed to the medical and nursing team in the following February, he received a knighthood.

Anaesthetic agents

The most commonly used agents in the 1920s were nitrous oxide, ether and chloroform.

NITROUS OXIDE

Nitrous oxide, oxygen and ether had been a popular sequence since the time of Clover, and nitrous oxide and oxygen were often given to accompany local or regional blocks. Other uses of nitrous oxide as the sole agent were inevitably accompanied by hypoxaemia. The technique described by Hewitt in 1893[35] where induction was with 100% nitrous oxide, and a small percentage of oxygen (usually less than 10%) was then added, was widely used for brief operations and in the dental chair. The patient was invariably cyanosed and sometimes jactitated.

McKesson described his secondary saturation technique in 1920[52] and modified it in 1926; 100% nitrous oxide was given first (primary saturation), oxygen under pressure was added to improve the patient's colour, followed by more nitrous oxide (secondary saturation) and oxygen alternately. The technique was condemned by Gwathmey, and Boyle said that it frightened him.[35] It was defended by Sykes, who thought the results were good in McKesson's hands.[71]

Nunn has commented on the apparent acquiescence of the 19th century anaesthetists in hypoxaemia[60] and this continued until well into the

(*Br. J. Anaesth.* 1998; **80**: 96–103)

Keywords: history, anaesthesia

P. M. E. DRURY, MA, MB, BCHIR, FRCA, Member of Council, History of Anaesthesia Society, 80 Green Lane, Liverpool L18 2ER.

present century. Nevertheless, nitrous oxide was regarded as a safe anaesthetic, with few attributable deaths. Smith has suggested that the body can tolerate a brief period of acute hypoxaemia, but has speculated on the intellectual cost.

In 1926, the anaesthetic section of the Royal Society of Medicine[50] discussed the purity of the gas in cylinders of nitrous oxide at some length, and agreed that 95% was acceptable. At this time cylinders were not pin-indexed or colour coded. In 1930 a five theatre block with piped gases was opened at St Bartholomew's Hospital in London.[34]

ETHER

Despite manifest disadvantages, ether owed its continuing use in this decade and beyond to the maintenance of circulatory stability at high inspired concentrations, and to its ability, also at high concentrations, to produce abdominal relaxation, which approached that provided by today's relaxants. In these respects it had no real rivals. But it was flammable and explosive, and its after effects were extremely unpleasant. They were vividly described by Henderson and Coburn[33] in the following terms: "patients.... were flaccid, cyanotic, pallid, or grey, with empty veins, weak peripheral pulses, and depressed respiration; it was one to three hours before consciousness returned, and this was followed by nausea, vomiting, and retching for some time afterwards".

CHLOROFORM

Controversy continued to surround this agent. The opinion that "chloroform should be discarded" may well have been expressed in the 1920s; in fact the quotation is from the 19th century. The American Medical Association sought a ban in 1912. In 1923 a "famous" London hospital had 42 chloroform fatalities in 8 weeks, and a correspondent to the *British Medical Journal* regretted that "week after week the chloroform holocaust goes on".[55]

In 1922, Levy published his monograph, *Chloroform Anaesthesia*[41] in which he identified a previously unrecognized cause of death, that of ventricular fibrillation in light anaesthesia, which could also be precipitated by the use of epinephrine. He and others who recognized the hazards gave rules for safe administration, but there were enthusiasts who claimed never to have had any problems. Chloroform was cheap, easy to administer and not explosive. This enigmatic agent was still attracting contributions to the literature in the 1970s.[63]

OTHER INHALATION AGENTS

Ethyl chloride was well established and *di-vinyl ether* appeared at the end of the decade. Both were suitable for brief administrations but were too toxic for more prolonged use.

Acetylene (1922) and *ethylene* (1923) were greeted initially with some optimism because they could be used as the sole agent with an adequate concentration of oxygen, but they had an unpleasant garlic-like odour, were explosive and showed no clear advantage in terms of postoperative nausea and vomiting. They never really became established in the UK.

Cyclopropane became more widely used in the 1930s, but made its first appearance in the literature in 1929. The second human guineapig to receive it was none other than the Nobel laureate Frederick Banting. It was possibly the first agent the cost of which caused some surprise.

The curious episode of *ethanesal* should be mentioned. Boyle and Hewer wrote favourably of this agent,[6] which was ether containing ethylene, carbon dioxide and "potent ketones". There was an erroneous belief that pure ether was not an anaesthetic but merely acted as a solvent for more potent substances. Following unfavourable comments by the American Medical Association and thorough testing by Dale, Hadfield and King[15], ethanesal passed quickly out of use.

NEUROMUSCULAR BLOCKING AGENTS

De Caux used an aqueous solution of curare i.v. in seven patients at the North Middlesex Hospital in 1928. Nothing was published at the time, but Goldman recalled discussing the cases with de Caux and referred to them in a book in 1948.[74] It seems to have been an isolated occurrence.

Techniques and equipment

OPEN METHODS

The technique most commonly used in this decade was still the open drop method[56]; ether and chloroform were given in this way. The liquid was poured from a bottle with a dropper onto gauze held in a wire-framed mask. The face and eyes were protected with material such as gamgee. The liquid had a tendency to freeze on the gauze, reducing the evaporating surface and requiring a change from time to time. Mixtures of chloroform and ether were also given by this method, the most popular being two parts chloroform and three parts ether (C_2E_3) or alcohol, chloroform and ether (ACE) in the ratio 1:2:3. The evidence that they modified the disadvantages of ether or made chloroform safer is not convincing.

BOYLE'S MACHINE

Boyle's machine first appeared in 1917 and was presented to the anaesthetic section of the Royal Society of Medicine in 1918. In its original form it consisted of nitrous oxide and oxygen cylinders, a water sight feed bottle for indicating gas flows and an ether vaporizing bottle, all mounted on a platform with wheels. The cylinders had reducing valves, but because the nitrous oxide was not dry they had a tendency to freeze, and a spirit lamp was provided to keep them warm. The gases were admitted to the ether bottle by a tap. This design underwent modifications so that by 1930 there was a second vaporizing bottle (for chloroform), a third water sight feed tube (for carbon dioxide) and a plunger device on the vaporizing bottle. Boyle readily acknowledged the influence of Gwathmey in his design; a Gwathmey machine was shipped to England in 1916 and used by Boyle as a model.[31]

Boyle's machine did not immediately displace all others; there is evidence that some older equipment continued in use for some time.[25] Magill, in his early communications, recommended Shipway's apparatus. Some anaesthetists had machines to their own design. J. Ross McKenzie of Aberdeen persuaded Coxeter to make a machine for him that would give nitrous oxide, oxygen, carbon dioxide, ethylene, propylene and acetylene.[51]

Another important machine, involving a new principle and to prove of lasting worth in the field of dental anaesthesia and self-administration, was the intermittent flow apparatus shown by McKesson at the British Medical Association meeting in 1926.[54]

INTRATRACHEAL ANAESTHESIA

In 1965, Armstrong Davidson wrote,[16] "Intubation was the most important advance in technique since the introduction of anaesthesia". Although not the first description of tracheal intubation, Rowbotham and Magill's account in 1921 of their solution to the problems posed by the patients at Gillies' Plastic Surgery Unit at Sidcup, Kent, is regarded as the origin of today's routine practice.[66] Mask techniques were not applicable as the majority of operations were on the face. Nitrous oxide, oxygen and ether were insufflated via an intratracheal catheter, but an expiratory tube was also provided. Initially this was a nasopharyngeal tube; later, a second intratracheal catheter was used, and finally a single wide bore red rubber tube.[44]

The tubes were passed using a direct vision laryngoscope. The design was not specified, but Magill did invent his own based on Chevalier Jackson's straight bladed instrument. Rowbotham performed a blind nasal intubation in 1920, and Magill by his description in 1930, hoped that the technique would become more widely used.[45] He was not in favour of routine intubation because he believed that anaesthetists should be skilled in maintaining an airway.

Intratracheal anaesthesia was not at first universally accepted, and there were those who were concerned about ill effects, including surgeons. Hewer recorded the deception of covering the intratracheal tube with a mask. The addition of an inflatable cuff to wide bore tubes was described not by Magill but by Guedel and Waters.[28] Magill and Rowbotham used throat packs where aspiration was a risk.

I.V. AGENTS

The days of the ultra-short acting barbiturates were yet to came, but the first description of the use of barbiturates i.v. was in the 1920s; a considerable amount of literature came from Europe.[1] An early British publication was that of McDonald in 1926.[48] He gave an account of the use of somniferine as a basal hypnotic before abdominal surgery, performed under regional block combined with light general anaesthesia. Lundy (who was largely responsible for furthering the cause of thiopental) used pentobarbital i.v. at the Mayo Clinic.[43] He defined four stages from sedation to very deep unconsciousness, where some surgery was possible, but it was accompanied by severe hypotension, respiratory depression and the need to maintain an airway. The lengthy period of recovery running into hours was no surprise to those familiar with ether anaesthesia. Lundy also mentioned the successful treatment of convulsions with this drug.

Constantin (1929)[14] gave details of a technique using 96% ethyl alcohol in glucose i.v. as the sole agent for abdominal surgery. Surprisingly, expected side effects of headache, nausea and vomiting were not mentioned. This increasing interest of anaesthetists in i.v. agents implied that, for the first time, they came to be regarded as experts at venepuncture.[11]

RECTAL ADMINISTRATION

As with i.v. agents, the initiatives for rectal administration came from outside Britain. Gwathmey was an enthusiast for rectal administration of oil/ether.[29] Blomfield felt that the rectal route was useful "in certain circumstances". Rowbotham felt that basal narcosis with rectal barbiturates was a considerate way to treat children.[65] The discovery of Avertin (bromethol) in 1929 led to its increased use in general surgery and obstetrics, but not as the sole agent.[13]

LOCAL AND REGIONAL ANALGESIA

The majority of techniques in use today were in place in the 1920s. Labat's very comprehensive textbook was published in 1923.[38] Labat was an anaesthetist, and anaesthetic texts always carried a section on local and regional analgesia, but a considerable number of blocks were performed by surgeons, and the extent of anaesthetists' involvement is not always clear. Lee's article on Barker[40] suggests that this pioneer of spinal anaesthesia believed that the technique fell within the province of surgeons. On the other hand, Whitehouse felt that surgeons were trespassing in the anaesthetic field.[72]

Spinal anaesthesia had been used for operations on the head and neck, but a common view held at this time was that they were most useful in operations below the umbilicus.[22 34] The range of suggestions for use is wide, and includes abdominal emergencies such as intestinal obstruction, where its use is less likely today. Spinal anaesthesia was also suggested for the treatment of ileus.[70]

The local anaesthetic drugs used were commonly procaine, the withdrawn CSF being used to dissolve the crystals, and stovaine. Cocaine was by now confined to surface analgesia. Cinchocaine appeared in 1929.[37] Discussions about light and heavy preparations and positioning the patient seem less relevant today. The significance of using small bore needles was recognized.[62] Neurological complications undoubtedly occurred, but were not given great prominence.

The usual approach to the extradural space in this decade was via the sacral route. It was not realized until later that Pages, a surgeon in Madrid, had published an article in 1921 in which lumbar, thoracic and cervical approaches were mentioned. When Dogliotti of Turin described lumbar extradurals in 1931, he was not aware of Pages' work, but later acknowledged it.

Surgery

ABDOMEN

The surgeons of the 1920s would have welcomed the degree of relaxation of the abdominal wall which is now an everyday occurrence; it was often a struggle to close the abdomen. Comparable conditions could be produced by spinal anaesthesia, and also by paravertebral, intercostal or rectus sheath block, supported by coeliac axis block, but occasionally a covering light general anaesthetic was given because of patchy analgesia, or a spinal block that was not high enough. Hewer recommended the insufflation technique used in thoracic anaesthesia (see below), but statements that agents such as ethylene or chloroform produced reasonable relaxation somehow lacked conviction. When McKesson discussed his secondary saturation technique at the Royal Society of Medicine in 1926, it was felt by some speakers that the degree of muscle rigidity would not be accepted by English surgeons.[53]

BALANCED ANAESTHESIA

Crile was a strong advocate of a combination of local and light general anaesthesia with nitrous oxide (anoci-association). He argued that if all afferent stimuli including fear were abolished the patient would not suffer shock and its consequences. Although his work is much quoted, it is difficult to know to what extent his ideas were put into practice. One author thought that lip service was paid to them while people continued to pour quantities of ether and chloroform on to masks. Even in Europe where these methods were commoner, it was felt that Crile's work was not as well known as it should have been.[23]

Although many routine surgical procedures are unchanged, our predecessors in the 1920s faced many problems that do not exist today.

THORAX

Surgery was an important part of the treatment of tuberculosis, using such procedures as rib resection for empyema and thoracoplasty, which could be quite extensive, for reducing the size of cavities. Lobectomy was on the increase towards the end of the decade,[18] but pneumonectomy was not yet established. Chest wall procedures could be carried out satisfactorily under local anaesthesia. Other procedures were performed with combinations of local anaesthesia, sedation, narcosis and general anaesthesia which varied from centre to centre. As there were no antibiotics, and spread of the disease within the lung was feared where sputum was plentiful, there was a demand for a plane of anaesthesia which preserved the cough reflex, an exacting requirement in the days before one-lung anaesthesia, double-lumen tubes and bronchus blockers.

The usual solution to the pneumothorax problem was intratracheal insufflation of nitrous oxide, oxygen and a volatile agent, usually ether, under sufficient pressure (10–20 cm H_2O) to maintain some expansion of the lungs. Respiratory movements were much diminished or even absent, yet oxygenation remained good through diffusion. Periodic deflation of the lungs was necessary to maintain venous return. The technique was developed clinically in America by Elsberg.[21]

THYROID SURGERY

Many patients with florid Graves disease presented for thyroidectomy, as there was no effective medical treatment for thyrotoxicosis. There were no consistent recommendations for anaesthetic management, but it seemed widely agreed that chloroform was contraindicated. Crile believed that these highly nervous and excitable patients should not be told the day of their operation. They were given practice inhalations and injections of sterile water for a few days. On the appointed day, nitrous oxide, morphine and hyoscine were administered to the patient in bed; transfer took place to the operating theatre and the operation was completed with local anaesthetic supplement. This method was known as "stealing the thyroid".

OBSTETRICS

In operative obstetrics, all available anaesthetic techniques were used. There did not seem to be any awareness of the risk of regurgitation and inhalation of gastric contents.

CARDIAC SURGERY

There was occasional discussion in the journals on the role of surgery in valvular heart disease.[59] Souttar performed a transauricular split of the mitral valve at the London Hospital in 1929.[20] The anaesthetic was administered by Lindsay, a surgical colleague, using open drop ACE mixture at induction and intratracheal nitrous oxide, oxygen and ether by insufflation.

The perioperative period

PREPARATION

The statement that preoperative purgatives and enemas should be phased out[2] suggests that the practice was continuing in some quarters. On the other hand, there was encouragement to give adequate fluid up to the time of operation, although the route of administration was not specified.

PREMEDICATION[67 68]

Although the word may have been used informally, the first mention of it in print seems to be by McMechan in 1920. Previously, terms such as preliminary medication or pre-anaesthetic medication were used. The drugs available were atropine, morphine and hyoscine. It is surprising how little those drugs were used preoperatively in this country before 1911, when there was increased interest in their properties. Sometimes they were all given together, and although respiratory depression prolonged induction with ether, it also made it smoother. But despite reduction of apprehension, some surgeons and anaesthetists were unhappy about the use of both morphine before operation, especially before chloroform, and of hyoscine, which was thought to contribute to increased muscular rigidity.

Atropine was the only drug which could be said to have been prescribed routinely, particularly for its effect in reducing the considerable bronchorrhoea stimulated by ether. It was also advocated before the administration of chloroform as protection for the heart, particularly against vagal overactivity. There is some doubt surrounding this proposition, and as Levy pointed out, the use of atropine did not prevent chloroform deaths.[41]

The term "twilight sleep" was given to the practice of injecting morphine and hyoscine in generous doses in the labour ward, with additional doses of hyoscine to produce amnesia. The price of this was an increased degree of restlessness.

RISK ESTIMATION

There was no ASA classification or Goldman multifactorial risk index, but there were some attempts to assess preoperative cardiac status. Goodall believed that every general hospital should have a cardiac department where routine preoperative examination of surgical patients could be done.[26] Blomfield emphasized the significance of dyspnoea as a symptom, and believed that information from exercise testing and breath-holding was important. Moots[59] proposed some quantitive tests, such as the pressure ratio (pulse pressure/diastolic pressure, range 30–70%) and the energy index (the product of the sum of systolic and diastolic pressures, and heart rate; range 12–18 000), which is similar to the more recent concept of rate–pressure product.

MONITORING

Much monitoring must have been rudimentary. With two hands occupied holding a face mask, or pouring liquid on to gauze, visual assessment of respiration and colour would have been the main observations, with occasional palpation of the pulse and examination of the pupils. Guedel's signs had been published in 1920.[27] Recent studies have demonstrated that detection of cyanosis is not always reliable,[12], even by experienced observers, so that some degree of hypoxaemia must have been common, especially in patients breathing air.

From the standpoint of the 1920s, the recording of arterial pressure was relatively new. Hewer considered that it should be recorded every 5 min during abdominal surgery and recorded on a graph.[34] He used a brachial artery stethoscope and a cuff. Mennell, of St Thomas', who worked with the eminent neurosurgeon Sir Victor Horsley, also emphasized the important of frequent readings.[58] Investigations were beginning into the indirect measurement of venous pressure in relation to anaesthesia.

RESUSCITATION

In an era when techniques of cardiopulmonary resuscitation are widely taught, it might be thought that our predecessors were not so skilled in this area. Information was rather scattered in various texts, and as a considerable number of anaesthetists were self-taught, it would be a matter of chance whether the necessary knowledge was to hand. Nevertheless, there were some effective techniques for the treatment of respiratory and circulatory failure.

Various methods of artificial respiration, such as the Silvester, had been described from the 1850s. Compression of the chest is also described,[8] so that some patients may have unwittingly received external cardiac massage. Mouth-to-mouth respiration is mentioned by Levy and others as a little known technique which deserved a wider awareness.[41] If an intratracheal catheter was in place it could be used for insufflation; it could also be blown down, or attached to a pump or bellows (perflation). It does not seem to have occurred to anybody to squeeze a rebreathing bag.

Internal cardiac massage was in the repertoire. If the abdomen was open the heart was approached through the diaphragm, otherwise an intercostal incision was made. Intracardiac epinephrine was also used. Although these methods were undoubtedly effective in some cases, there are no values for success rates.

Treatment of hypovolaemic shock was less confident. The feasibility of blood storage[64] and person to person transfusion had been demonstrated during World War I, but there were no blood banks, and registration of donors was only just beginning. There was a reluctance to use the i.v. route except as a last resort,[69] despite wartime experience with gum solution as a plasma expander.[3]

Stimulant drugs such as strychnine had been in use for some time. Ephedrine was introduced in 1924.

POSTOPERATIVE CARE

The treatment of postoperative pain has a low profile in the literature of this period. Because of more prolonged recovery from anaesthesia, it did not require the early attention that it does today, but presumably patients were handed over to nursing staff and given morphine i.m. One thoracic surgeon prescribed morphine for his patients for 12 days. The rectal route was sometimes used for administering analgesia combined with sedation, for example aspirin and bromide. Maintenance fluids were seldom given i.v., but more usually by the rectal route or subcutaneously.

More thought was given to the problem of postoperative vomiting, although treatment was empirical. There were no specific antiemetic drugs; atropine and hyoscine had antiemetic properties but were used for other reasons. A variety of hot and cold liquids, medicinal, mineral waters, beverages and also alcoholic drinks such as brandy and champagne had their advocates. It had to be borne in mind that not all postoperative vomiting was related to the anaesthetic; the cause was sometimes surgical. It was hoped that the use of warmed intratracheal ether, and also Henderson's de-etherization technique with carbon dioxide,[33] would reduce the incidence of vomiting. The possibility of recovery wards was raised by Flemming,[24] but he was concerned that surgeons voracious for beds would seize them.

Insulin, of which limited supplies started appearing in 1923, was becoming more widely available.

COMPLICATIONS

The Section of Anaesthetics at the Royal Society of Medicine discussed deaths in April 1923.[10] Mennell was able to assure them that every death during anaesthesia at St Thomas' was investigated by a subcommittee consisting of an anaesthetist, pathologist and a surgeon. Many cases were unrelated to anaesthesia, but in some it played a principal part. Flemming pointed out that the death rate associated with operation was stationary, despite an increase in the number of administrations. It is to be hoped that the report of three deaths in one day at Poplar Hospital, which was the subject of a question in parliament,[36] was an aberration, although it suggests incompetence.

Some members were concerned that it was a statutory requirement to report on deaths on the table to the coroner, who then usually held an inquest. There was unhappiness about the quality of newspaper reporting, and the fact that these deaths were classified by the Registrar General as anaesthetic deaths. There was no requirement to report postoperative deaths (some of which might have been associated with anaesthesia).

Post mortem was generally unhelpful where there was no gross pathology, fatty degeneration of the heart being a useful label. Status lymphaticus,[7] a syndrome characterized in young people by lymphoid hyperplasia, was a recurring diagnosis, although it later lost its validity. In a retrospective review, McIntosh[49] considered that this diagnosis obscured the fact that death was caused (then as now) by failure to maintain an airway. He also demonstrated that coroners were frequently lenient in finding no fault with the treatment. There was a reminder that death could also occur with local anaesthesia.[47] Mayer described 46 cases in 1924, 26 caused by cocaine.

Pinson[61] estimated in 1930 that there were at least 100 fires and explosions annually in theatre. Many of these resulted in injuries of a minor nature, but there were some deaths. The increasing use of diathermy, for coagulation and debulking of tumours, was an additional risk factor.

In the first issue of *Current Researches in Anesthesia and Analgesia*, an editorial by McMechan implied that the death of a Dr Curtain was associated with the administration of 30 000 ether anaesthetics. The author regretted that medical science provided no protection from this, whereas it did provide for the protection of radiologists.

Literature and postgraduate activity

BOOKS

McIntosh is quoted as saying at this time that the only means of acquiring knowledge beyond the basics was to study books published abroad.[4] Presumably he was referring to Gwathmey's book,[29] the second edition of which was published in 1925. Two well established British books appeared in new editions; a sixth edition of Buxton's book of 1888 appeared in 1920[8] and a fifth edition of Hewitt's book of 1893[35] was published in 1922. Hewitt died in 1916 but the new editor, Robinson, kept the name. Blomfield produced a fairly substantial book of 424 pages in 1922,[5] which was well reviewed in the *British Medical Journal*, but as Zuck[76] has pointed out, there was no major British specialist textbook published between 1922 and 1947. Other influential names did not enter the field until the 1930s (Guedel, Lundy, Minnitt, Waters). Some surgical books contained a chapter written by an anaesthetist (e.g. Magill[46]).

JOURNALS

The first issue of *Current Researches in Anesthesia and Analgesia* appeared in 1922; it was a continuation of the proceedings published by the National Anesthesia Research Society Inc. It was edited by McMechan, who had also been responsible for the twice yearly anaesthesia supplement in the *American Journal of Surgery*, which had started in 1914. Once *Current Researches* became established, these supplements were phased out.

The *British Journal of Anaesthesia* was a new venture for the UK, although with a target of 500 subscribers it was looking for international recognition. The price was 10s 6d for a single issue and the editor pronounced himself satisfied with progress at the end of the first year. It was his ambition to publish the journal monthly.

An earlier source of printed material was the anaesthetic section of the Royal Society of Medicine, which was published in the proceedings, and which had been formed in 1908 with more than 100 members.

It should be acknowledged that the general medical journals, the *British Medical Journal* and the *Lancet*, and the *Journal of the American Medical Association* were reasonably generous in providing space for matters of interest to anaesthetists. Some of it took the form of abstracts and reports of meetings, but there was also representation in articles, editorials, book reviews and correspondence.

SOCIETY MEETINGS

The British Medical Association Annual Scientific Meeting had an anaesthetic section from 1920. In 1925, A. R. Cox, the secretary of the British Medical Association, met McMechan at an international congress and invited him to the next meeting in Nottingham. This was the first time that associations from Britain and North America had met and it cemented transatlantic friendships that had begun in World War I. McMechan was later elected honorary associate editor of the *British Journal of Anaesthesia*.

There was a Scottish Society of Anaesthetists formed by a group of general practitioners in 1914. The first provincial society in England was the Liverpool Society of Anaesthetists (1930). Anaesthetists did of course give papers to local medical societies.[36]

ANAESTHETIC DEPARTMENTS

In 1927, the Dean of a new medical school at the University of Wisconsin approached some of his contemporaries with a view to setting up university departments; among them was Ralph M. Waters. He is quoted as saying[73] that the formation of the specialty depended "first upon men, second upon publications, and third upon organisations through which men meet for mutual development by exchange of ideas". The reputation of his department grew steadily, and it attracted visitors from all over the world. Among them was McIntosh, the holder of the first British chair at Oxford, who later paid a very warm tribute to Waters.[50]

Another significant appointment at this time was that of J. S. Lundy at the Mayo Clinic. In addition to his work on i.v. agents, he developed an anatomy laboratory.[17]

FUTURE ASPIRATIONS

In the first issue of the *British Journal of Anaesthesia*, the editor had a wide ranging view of the future of the specialty, although the reality had to wait until the formation of the Association of Anaesthetists in 1932. Cohen returned to the subject in an editorial in January 1927, starting with the premise that the present state of anaesthetic instruction was not worthy of such an important branch of surgery. "Nothing less than a well-equipped Department or School, with paid instructors capable of teaching all the various types of general and regional anaesthesia, as well as Physiology, Chemistry, and the Mechanics of the Subject will suffice".

The president elect of the British Medical Association, Sir Robert Philip, who had for a time acted as an anaesthetist for Thomas Keith of Edinburgh, a pioneer of ovariotomy, addressed the Section of Anaesthesia at the 1926 Scientific Meeting, and said that the satisfactory practice of anaesthesia rested ultimately in physiology. The anaesthetist would be a physician in the best sense of the word.

The anonymous obituarist of H. W. Webber (1955) thought that 1922 was a year when widening knowledge had begun to stir the rather static world of anaesthesia. The stage was now set for further advances in the 1930s.

Conclusion

Although anaesthesia was still crude in some ways, the 1920s saw many developments. The wider use of tracheal intubation, introduction of anaesthetic machines and appearance of new journals are some examples that have been mentioned above. More doctors were becoming interested in anaesthesia as a specialty, and there was movement towards a wider role beyond mere administration of gases. The appearance of the first recognized department of anaesthesia devoted to teaching and research was an important pointer for the future.

CITATION CLASSIC

Commentary

Prys-Roberts C, Greene LT, Meloche R, Foëx P. Studies of anaesthesia in relation to hypertension. II: Haemodynamic consequences of induction and endotracheal intubation. *British Journal of Anaesthesia* 1971; **43**: 531–547.

This frequently cited article by Prys-Roberts and colleagues is one of a series by this group of investigators in the early 1970s that assessed the effects of anaesthesia, tracheal intubation and ventilation in treated and untreated hypertensive patients compared with normotensive patients.[1 2] The article that I will comment on examined specifically the haemodynamic response to induction of anaesthesia, and subsequent laryngoscopy and tracheal intubation in treated and untreated hypertensive patients. As I discuss the content and clinical implications of this investigation, it will become obvious why this article became a citation classic of the *British Journal of Anaesthesia.*

The study was performed in the following way. Arterial pressure, heart rate and the electrocardiogram were monitored continuously in 16 untreated and 20 treated adult (aged 24–72 yr) hypertensive patients during and after induction of anaesthesia, laryngoscopy and tracheal intubation. Anaesthesia was induced with either thiopental 50–200 mg (n = 15), methohexital 80–100 mg (n = 6), propanidid 200–300 mg (n = 4), diazepam 10–20 mg (n = 2) or neuroleptanalgesia (phenoperidine 0.8–1.6 mg, droperidol 5–9 mg, n = 9). After loss of consciousness, patients breathed a mixture of 1% halothane in nitrous oxide 7 litre min^{-1} and oxygen 3 litre min^{-1} for 5–10 min until arterial pressure and heart rate had stabilized (i.e. steady state after induction). Subsequently, succinylcholine 75–100 mg was administered i.v. Approximately 2 min later, laryngoscopy was performed (with the laryngoscope held in position for 15–20 s), the larynx and trachea were sprayed with 4% lignocaine 2 ml, and the trachea intubated. After intubation, the same gas mixture as that used before intubation was used to maintain anaesthesia. Spontaneous respiration was allowed to return and to continue undisturbed until arterial pressure and heart rate had stabilized (i.e. steady state after intubation). Four additional patients underwent blind nasal intubation.

Of the numerous results of this investigation, the most relevant clinically can be summarized as follows. First, in untreated and treated hypertensive patients, induction of anaesthesia and subsequent tracheal intubation were associated with pronounced swings in arterial pressure. Whereas the absolute decrease in arterial pressure after induction of anaesthesia was greater in untreated patients, the incidence of hypertension exceeding conscious control values was higher in the treated patients (70 *vs* 42%).

Second, in the majority of patients, maximum increases in arterial pressure and heart rate occurred during laryngoscopy but before intubation. In contrast with arterial pressure, heart rate increased to values above awake control values in both groups of patients. The increase in heart rate was accompanied by a 40% incidence of arrhythmias which persisted for 2–3 min after intubation. The hyperdynamic cardiovascular response was short lived.

Third, there were no significant cardiovascular changes during blind nasotracheal intubation.

On the basis of these findings the authors concluded that "... hypertensive patients are as much if not more at risk during induction of anaesthesia, and during subsequent laryngoscopy and tracheal intubation, as they are during steady-state anaesthesia". They continued that "... it was surprising to find that patients on anti-hypertensive therapy with well controlled arterial pressures, were equally prone to develop a hypertensive response to intubation ...". These are valid and clinically important conclusions which nevertheless require additional comments to put them into perspective.

By today's standards many of the "treated" hypertensive patients would be categorized as poorly controlled (11 (55%) had diastolic pressures >110 mm Hg and 15 (75%) systolic pressures >160 mm Hg). Eleven patients had pathologically increased diastolic and systolic arterial pressures. Furthermore, the pharmacological approach to the treatment of hypertension has changed entirely in the past 25 yr. Methyldopa, reserpine, guanethidine, bethanidine, cyclopenthiazide and debrisoquine sulphate are no longer or very rarely used. Thus haemodynamic responses to various perioperative stimuli (including induction of anaesthesia, laryngoscopy and intubation) may differ quantitatively and qualitatively.

One might argue that the haemodynamic responses were not so much a function of increased baseline arterial pressures but rather that of the (low) dose of drug used to induce anaesthesia. Measurements during steady-state conditions after induction of anaesthesia were performed at 5–10 min after injection of the induction agents, measurements during laryngoscopy and intubation at 10–15 min, and those during steady-state conditions after intubation approximately 15–25 min after injection of the induction agent. Considering the progressively increasing time intervals between drug injection and measurements it is likely that the observed haemodynamic responses were determined primarily by the continuously breathed gas mixture of 1% halothane and 70% nitrous oxide.

Several other factors may have influenced the results. Most patients were not premedicated. The induction agents were not administered in random order but chronologically. The number of patients in most of the groups was too small to be able to make valid comparisons between drugs or between treated and untreated hypertensive patients. Normotensive patients were not included as controls. The statistical test used to compare data between treated and untreated patients was not mentioned, and the paired t test was used for multiple comparisons.

Despite such limitations, the investigation by Prys-Roberts and colleagues taught us a great deal. We learned that hypertensive patients are prone to greater variations in arterial pressure than normotensives. The excessive swings in arterial pressure associated with the sequence of induction of anaesthesia followed by laryngoscopy and intubation may lead to myocardial ischaemia in the susceptible patient (as indicated in figs 1 and 2 of the article). We learned that laryngoscopy and tracheal intubation are intense stimuli that can evoke a pronounced hyperdynamic cardiovascular response. Although most likely of no clinical consequence to the healthy patient (and probably not even to the patient with stable coronary artery disease because of the short-lived nature of the sympathetic stimulation), this response is potentially life-threatening for patients with symptomatic aortic or cerebral aneurysm, unstable coronary syndromes, recent myocardial infarction or intracranial hypertension.

The clinical implications of the various findings were numerous and continue to influence practice today. The results implied that it might be preferable to postpone elective surgery in the uncontrolled hypertensive patient until good control of arterial pressure has been achieved. Even 25 yr later, however, management of the hypertensive patient is still a matter of ongoing controversy.

The results indicated the importance of attenuating the cardiovascular response to laryngoscopy and tracheal intubation in patients at risk. Although deep levels of anaesthesia effectively and predictably blunt or even abolish the hyperdynamic circulatory response, such an approach may cause pronounced hypotension and bradycardia when the noxious stimulus has ceased, resulting in even greater arterial pressure swings. It might be preferable to attenuate the cardiovascular stimulation by topical anaesthesia, nerve blocks, i.v. lidocaine, α_2 agonists or β adrenoceptor antagonists.

The results clearly implied that the usual rapid-sequence induction of anaesthesia with a short-acting barbiturate followed by succinylcholine (preceded, at most, by a small dose of opioid) provides only minimal protection against the pressor and chronotropic effects of laryngoscopy and tracheal intubation. Limiting the duration of laryngoscopy (in this way minimizing stretching of tissue in the epi- and laryngopharynx) should be an effective preventive measure. Laryngoscopy exceeding 15–30 s seems to progressively stimulate cardiovascular reflexes. In accordance with the authors' findings during blind nasal intubation, fibreoptic nasal intubation blunts or, depending on baseline sedation, almost abolishes the increases in arterial pressure and heart rate during intubation.

No doubt the study by Prys-Roberts and colleagues considerably advanced our knowledge of the perioperative management of the hypertensive patient. It influenced daily anaesthetic practice and, although extremely difficult to quantify, possibly improved patient outcome. No less important, by posing numerous unanswered questions it triggered subsequent work in this area (for example, study on the means of attenuating the cardiovascular response to laryngoscopy and intubation, and on the mechanisms evoking this response). Perhaps most important, the data collected more than 25 yr ago have retained their clinical relevance. It is, therefore, of no surprise that the article by Prys-Roberts and colleagues has become one of the most cited in the history of the *British Journal of Anaesthesia*.

STUDIES OF ANAESTHESIA IN RELATION TO HYPERTENSION
II: HAEMODYNAMIC CONSEQUENCES OF INDUCTION AND ENDOTRACHEAL INTUBATION

BY

C. Prys-Roberts, L. T. Greene, R. Meloche and P. Foëx

SUMMARY

The electrocardiographic and haemodynamic responses to the induction of anaesthesia, followed by laryngoscopy and endotracheal intubation have been studied in a group of 16 untreated hypertensive patients, and a group of 20 patients receiving antihypertensive therapy up to and including the day of operation. The influence of five different induction agents, thiopentone, methohexitone, propanidid, diazepam, and neuroleptanalgesia induced by a combination of phenoperidine and droperidol were compared. Neuroleptanalgesia caused less arterial hypotension than any of the other agents, but afforded only marginally more protection than other agents against hypertension, tachycardia and dysrhythmia associated with laryngoscopy and tracheal intubation. Both propanidid and diazepam caused dramatic but transient hypotension in a small number of patients and were not investigated further. Unlike its effects in normotensive subjects, methohexitone caused greater hypotension than thiopentone in hypertensive patients. The rationale is presented for the prophylactic blockade of beta-adrenergic receptors to prevent hypertensive crises during laryngoscopy and intubation in both treated and untreated hypertensive patients.

During preliminary studies of the circulatory effects of anaesthesia in treated and untreated hypertensive patients (Prys-Roberts, Meloche and Foëx, 1971) we observed that most of the patients experienced three periods of circulatory instability: during induction, during and after tracheal intubation, and during the immediate period surrounding awakening. Tachycardia and hypertension are well documented complications of laryngoscopy and tracheal intubation in normotensive patients under a variety of anaesthetic techniques (Reid and Brace, 1940; Burstein, Lo Pinto and Newman, 1950; King et al., 1951; Rosner, Newman and Burstein, 1953; Takeshima, Noda and Higaki, 1964; Forbes and Dally, 1970) and during tracheal suction in patients with tracheostomy (Corbett, Kerr and Prys-Roberts, 1969). Dingle (1966) and Forbes and Dally (1970) suggested that the hypertensive response of normal subjects to laryngoscopy and intubation might be enhanced and prove dangerous to hypertensive subjects.

We have compared the haemodynamic effects of five agents for the induction of anaesthesia in treated and untreated hypertensive patients, in the hope of establishing the relative safety of each, and have studied the haemodynamic and electrocardiographic responses of these patients to the subsequent laryngoscopy and tracheal intubation.

CLINICAL MATERIAL AND PROCEDURES

The haemodynamic responses of 36 hypertensive patients were studied during the induction of anaesthesia, and during the sequence of short-term paralysis with suxamethonium followed by laryngoscopy and tracheal intubation. The patients were aged between 24 and 72, and were divided into two groups: those whose hypertension was untreated, and those who had been treated for varying periods of time with antihypertensive drugs, and who were receiving their drugs in the prescribed dosage up to and including the day of operation. Details of the patients are shown in table I.

Premedication: Dose in mg; Pa=papaveretum; Pt=pethidine; H=hyoscine; A=atropine.

Anti-hypertensive drugs: AMD=methyldopa; B=bethanidine; N–K=Navidrex-K (cyclopenthiazide with slow release potassium chloride); Dbq=debrisoquine sulphate.

*Resistance units: dyne sec cm^{-5}

The patients were interviewed and examined by one of us on the day preceding the study, and their consents to the observations were obtained after a full explanation of the purpose of the studies, and pre-operative assessment as described in full by Prys-Roberts, Meloche and Foëx (1971). Although most of the patients were not premedicated since baseline measurements on the conscious, undepressed, resting patient formed an integral part of the complete studies, some patients were premedicated according to their own or their anaesthetist's wishes.

The patients were brought to the anaesthetic room in their own beds, and lay in a supine position with one pillow throughout the studies. Under local analgesia, an 18-gauge Teflon cannula (Becton-Dickinson Longdwel) was inserted percutaneously into a brachial artery. In some patients, a larger version of the same cannula was inserted into the contralateral basilic vein, and a 90-cm nylon catheter was floated centrally until its tip lay in the right atrium, right ventricle or pulmonary artery. Standard electrocardiographic limb and chest leads were applied.

Arterial pressure was measured with a Statham P37 miniature pressure transducer connected directly to the arterial cannula, and right heart pressures were measured with a Statham PM131 TC transducer. Instantaneous heart rate was measured with a Neilson tachometer (Devices Ltd) triggered by the R wave of the e.c.g. Cardiac output was measured by the dye dilution method, using a Waters XC-302 cuvette densitometer and amplifier to detect and amplify the changing concentration of indocyanine green in arterial blood. All variables were simultaneously recorded on an Elema-Schönander EM 81 ink-jet recorder, and displayed on a four-channel oscilloscope (LAN electronics). Details of the methods were given in the previous communication (Prys-Roberts, Meloche and Foëx, 1971).

The choice of induction agent was determined chronologically; the first 15 patients received thiopentone sodium (2.5 per cent) in sufficient dosage (50–200 mg) to ensure loss of consciousness and acceptance of face-mask administration of the maintenance gas mixture—1 per cent halothane in nitrous oxide (7 l./min) and oxygen (3 l./min). The subsequent 9 patients were induced by neuroleptanalgesia (NLA) produced by incremental doses of phenoperidine (0.1 mg) and droperidol (1.0 mg) given over a period of 5–15 minutes until the patient appeared to be asleep (though responding to command) and accepted an anaesthetic facemask. The range of the accumulated doses of the drugs used to produce NLA were: phenoperidine 0.8–1.6 mg and droperidol 5–9 mg.

Four patients received propanidid (200–300 mg) in a 5 per cent solution, administered through the right heart catheter over a period of 15–20 seconds, followed by facemask administration of the maintenance gas mixture as soon as the hyperventilatory phase had commenced. Two patients were induced with 10–20 mg diazepam given over a period of 30 seconds, followed immediately by maintenance anaesthesia.

The last group of 6 patients received methohexitone (Brietal Sodium) in a dose of 80–100 mg, administered as a 1 per cent solution over a period of 30 seconds.

Prior to the moment of induction, all the patients were allowed to lie undisturbed for about 5 minutes while continuous recordings were made of the electrocardiograph (usually lead II), instantaneous heart rate, arterial pressure and right heart or pulmonary arterial pressures. Measurements of cardiac output were performed in duplicate during this period. The patients were not told when the induction agent would be administered, in the hope that pre-induction apprehension would not cause haemodynamic changes which would obscure the pharmacological effects of the induction agents.

Following the administration of the induction agent, the patients breathed the maintenance gas mixture through a Magill attachment and facemask for 5–10 minutes until arterial pressure and heart rate had stabilized. This stage was designated the post-induction steady-state period (1), and in many patients served also as a pre-intubation control period. In other patients, studies of baroreceptor function were performed during this interval, and a further measurement was made to serve as a pre-intubation control value during steady-state anaesthesia (2).

Endotracheal intubation.

When a steady state of spontaneous ventilation was established, suxamethonium 75–100 mg was administered intravenously, and when the muscle fasciculations appeared gentle manual inflation of

the lungs was started. It was established in an early group of patients that haemodynamic changes did not occur within the first 30–40 seconds if the lungs were not inflated, and that manual inflation for a period of 1 minute without further interference produced no significant changes from the control values. Laryngoscopy was therefore delayed for 20 seconds after visible fasciculations had ceased, and the laryngoscope (Macintosh) was held in position for optimal visualization of the vocal cords for 15–20 seconds before spraying the larynx and trachea with 2 ml of 4 per cent lignocaine. A cuffed oral endotracheal tube (Oxford pattern), lightly lubricated with lignocaine gel, was inserted and its cuff immediately inflated. Manual inflation of the lungs was maintained with the same gas mixture as that used before intubation, until adequate spontaneous ventilation had returned. The patients then breathed spontaneously for as long as was necessary to achieve a further steady-state (3) of ventilation and circulation.

Estimates of cardiac output, accompanied by sampling of arterial blood (and in some patients mixed venous blood) for estimation of Po_2, Pco_2 and pH, were obtained during the pre-induction control period, after the induction of NLA in the appropriate patients, during the post-induction and pre-intubation steady-state period, and finally during the post-induction steady-state period.

In 4 patients who underwent dental operations, blind nasotracheal intubation was performed after inhalation of approximately 8–10 per cent carbon dioxide in 60 per cent nitrous oxide and 30 per cent oxygen for about 60–90 seconds. The tube entered the larynx on the first attempt in every patient, and a pharyngeal pack was then manually inserted.

RESULTS

The data from this study are presented in two ways. Firstly as a comparison of the circulatory responses to the induction and tracheal intubation sequences in five groups of patients according to the induction agents used, each group comprising both treated and untreated patients. Secondly, as a comparison of the same sequences in two groups: treated (Group 1) and untreated (Group 2) hypertensive patients, irrespective of the agents used for induction.

Induction of anaesthesia.

Thiopentone. In 10 treated hypertensive patients (table II) a mean dose of 155 mg (SD 54) produced a 12 per cent fall of systolic arterial pressure within 3 minutes, and the steady-state values of both systolic and mean arterial pressures for the whole group were more than 25 per cent below the control values, and fell by more than 50 per cent in 2 patients, both female and over 65 years old, though with well controlled arterial pressure in everyday life. A 22 per cent fall in cardiac output was largely responsible for this arterial hypotension, since the systemic vascular resistance fell by only 4 per cent (n.s.). Heart rate increased transiently during the first minute without a significant change of arterial pressure, but the steady-state values of heart rate were not significantly lower than the control values.

In a smaller group of 5 untreated hypertensive patients (table II) arterial pressures fell progressively to a maximum of 35 per cent below the awake controls ($P<0.02$) during the steady-state period of maintenance, but unlike the treated hypertensive group, this arterial hypotension was predominantly due to a significant reduction of systemic vascular resistance (22 per cent, $P<0.05$), and although cardiac output fell by 0.72 l./min (mean), this difference did not reach statistical significance.

Neuroleptanalgesia. Before applying the face-mask, a state of neuroleptanalgesia (NLA) was achieved in which the patients would lie motionless, apparently asleep, but responding to command. In this state the mean arterial pressure was 15 per cent below the control value ($P<0.02$) in a combined group of treated and untreated hypertensive patients (table III). This fall was almost entirely due to a reduction of systemic vascular resistance ($P<0.05$). No significant changes occurred during the first 3 minutes after starting maintenance anaesthesia, but by the time a steady-state had been achieved, a further fall in both systolic and mean arterial pressures had occurred as a result of a 14 per cent reduction of cardiac output ($P<0.001$). No significant changes in heart rate occurred at any stage.

With one exception, there was no obvious difference between the responses of the treated and untreated patients in this group. One patient, a 70-year-old fit lady with untreated essential hypertension, developed a severe sinus bradycardia leading to heart block and hypotension within 4 minutes of the slow intravenous administration of droperidol 5 mg (fig. 1). She responded well to intravenous atropine (0.6 mg), but despite an increase in heart rate from 25 to 89 beats/min, she remained hypotensive (112/70 compared with 204/102 mm Hg) when full NLA had been established, and her cardiac output had fallen from 4.05 l./min to 2.74 l./min. Although the changes were transient in this patient, the findings emphasize the need for continuous monitoring of e.c.g., heart rate and arterial pressure in elderly hypertensive patients.

Propanidid. In a group of 3 untreated hypertensive and 1 treated hypertensive patients, all of whom had high arterial pressures at rest (table III), there was a significant reduction (32 per cent, $P<0.05$) of systolic and mean arterial pressures, together with a marked tachycardia, within 1 minute of completing the rapid intravenous administration of propanidid. After 3 minutes, there was little further change in the arterial pressure, though heart rate had returned to control levels. When a steady-state had been achieved, both systolic and mean arterial pressures were more than 32 per cent below the conscious resting values, with a moderate reduction of heart rate (18 per cent).

Diazepam. In 2 patients, diazepam caused marked but transient hypotension during the induction period (table III), and was associated with excessive hypertension following laryngoscopy.

Methohexitone. In 6 patients induced with methohexitone (2 treated and 4 untreated) there was a significant reduction of systolic (−19 per cent) and mean (−15 per cent) arterial pressure (table III), together with an 18 per cent increase of heart rate. Cardiac output changes were measured in only 1 patient in this group, whose values fell from 5.59 l./min in the awake control period to 3.98 l./min in the steady-state of maintenance anaesthesia. In this patient, there was a slight increase in systemic vascular resistance, thus the hypotension was entirely due to a decrease in cardiac output related to decreased stroke volume. The arterial hypotension was progressive during the first 5 minutes after induction, the values of systolic and mean arterial pressure in the steady-state period being 41 and 36 per cent respectively below the awake control values.

Since systolic pressures fell much more than the diastolic pressures during the first minute, it is probable that the hypotension at this stage was also largely due to reduced cardiac output rather than decreased vascular resistance.

Comparison of treated and untreated patients. There were significant differences ($P<0.05$) between the values of systolic, diastolic and mean arterial pressures in untreated and treated hypertensive patients during the awake control period, but not during any other stage of the investigations. The mean values for all variables after the induction of anaesthesia were remarkably similar in the two groups of patients at each stage of measurement (table IV). In the untreated hypertensive group, the greater fall in arterial pressure from the awake control to the steady-state value was associated with a greater reduction of systemic vascular resistance (2269 to 1993 dyne sec cm^{-5}) compared with the treated hypertensive patients (1925 to 1811 dyne sec cm^{-5}), though the difference between the two groups did not reach statistical significance at the 5 per cent level.

Sequence of tracheal intubation.

Thiopentone. In 10 treated hypertensive patients, no significant change of arterial pressure or heart rate occurred following the administration of suxamethonium (75–100 mg) intravenously. The maximum values of systolic, diastolic and mean arterial pressures, and of heart rate occurring within 30–60 seconds of laryngoscopy and intubation, were significantly higher than the steady-state values during maintenance anaesthesia (table II), and the mean values for the group following laryngoscopy were almost identical with the awake control values for arterial pressure, but heart rate was significantly higher ($P<0.05$) than in the conscious patient. Three patients had systolic arterial pressures not more than 50 mm Hg higher than their conscious values, and one patient exceeded his conscious systolic arterial pressure by 92 mm Hg. The steady-state values achieved after intubation did not differ significantly from those before intubation.

TABLE III

Circulatory responses of four mixed groups (treated and untreated) of hypertensive patients to induction of anaesthesia with neuroleptanalgesia (group A), propanidid (group B), methohexitone (group C) and diazepam (group D), and the subsequent sequence of muscular paralysis, laryngoscopy and endotracheal intubation, and maintenance anaesthesia. Mean values are shown with SD in brackets.

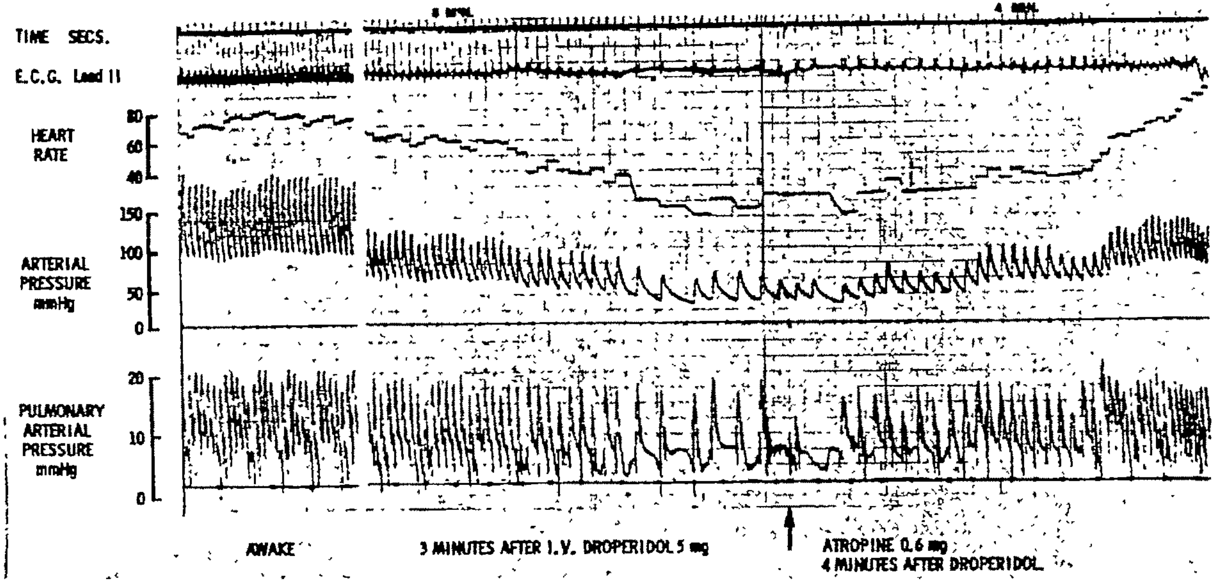

FIG. 1

Development of marked sinus bradycardia leading to heart block following the administration of droperidol (5 mg) in patient No. 21, and the return to sinus rhythm following atropine (0.6 mg).

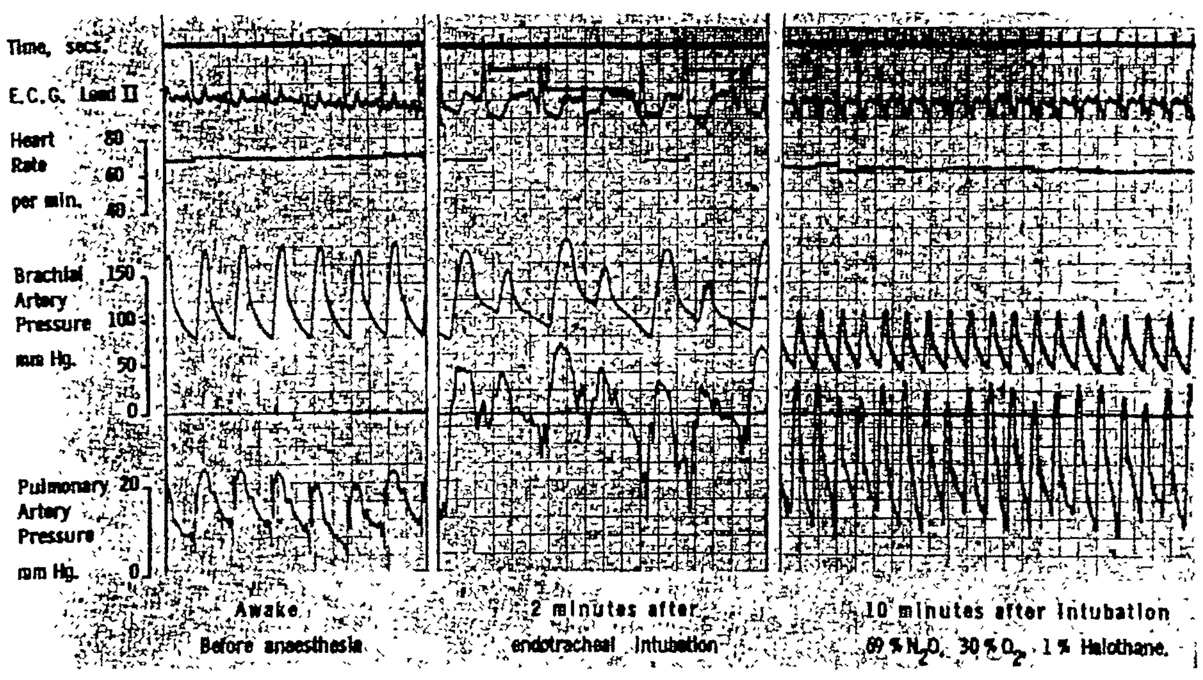

FIG. 2

Circulatory changes occurring during and after laryngoscopy and tracheal intubation (patient No. 15). The lefthand panel shows the values during the awake control period, at which time the patient's cardiac output was 4.27 l./min. Arterial hypertension occurred within 15 seconds of laryngoscopy, despite having fallen to 100/50 mm Hg after induction. Tracheal intubation was accompanied by prolonged ventricular bigeminy and further systemic hypertension. Pulmonary hypertension was also noted at this stage (centre panel) and persisted into the steady-state of maintenance anaesthesia. Depression of the S-T segment and T-wave inversion also persisted into maintenance anaesthesia, indicating myocardial ischaemia in association with the low arterial pressures. Cardiac output fell to 2.84 l./min during maintenance anaesthesia; thus, in association with the elevated pulmonary arterial pressures, it may be estimated (even in the absence of left atrial pressures) that the resistance of the pulmonary vascular bed had more than doubled.

Similar directional changes were observed in 4 untreated hypertensive patients (table II), and although the data are not amenable to statistical comparison because of the small numbers in this group, the mean values for all variables are sufficiently similar to those of the treated hypertensive group, at each stage, that it is unlikely that a real difference exists.

Neuroleptanalgesia. No significant changes in arterial pressure or heart rate accompanied the administration of suxamethonium to 9 patients induced by neuroleptanalgesia (table III). The changes which followed laryngoscopy and intubation were of a similar magnitude to those in patients receiving thiopentone, and there was no significant difference between these values for arterial pressure and those in the awake control period, although heart rate was elevated by 18 beats/min ($P<0.02$). In individual patients, the systolic arterial pressure after intubation exceeded their awake controls in 5 patients, 1 of whom had an increase of 66 mm Hg.

Propanidid. No significant haemodynamic changes accompanied the administration of suxamethonium in 4 patients induced with propanidid. Arterial pressures increased significantly (table III) following laryngoscopy and intubation, and the mean values for the group were not significantly different from the awake control values. Systolic arterial pressure exceeded the awake control in 2 patients, one by 22 mm Hg, and in the other by 76 mm Hg reaching a maximum value of 276/176 mm Hg. Heart rate also increased significantly in the group as a whole, although the fastest rate recorded (96) was rather lower than the fastest rates recorded in the thiopentone group (7 out of 10 developed heart rates in excess of 100) and the NLA group (maximum rate 140 beats/min, 3 out of 9 over 100 beats/min).

Methohexitone. There was a greater percentage increase in systolic and mean arterial pressures (53 per cent, $P<0.05$) following laryngoscopy and intubation (table III), as compared with the other groups (thiopentone 39.4 per cent; NLA 27 per cent; propanidid 51 per cent). Individual systolic pressures exceeded the awake control values in 2 patients, +39 mm Hg in one and +72 mm Hg in the other.

Comparison of treated and untreated patients. Mean values for arterial pressures, heart rate and cardiac output in the pre-intubation steady-state were not significantly different in the two groups of patients (table IV), and the administration of suxamethonium had no significant effect in either group. Following laryngoscopy and intubation, arterial systolic, diastolic and mean pressures, and heart rate were significantly elevated as compared with the pre-intubation steady-state, and there was no difference between the responses of the treated and untreated patients. Postintubation steady-state values were similar in both groups, and were not significantly different from the pre-intubation levels. Following intubation, there was a higher incidence of hypertension exceeding the awake control value in the treated hypertensive patients. Mean arterial pressure was elevated above control values in 70 per cent of this group as compared with 42 per cent of the untreated hypertensive patients, and 4 treated hypertensives had excessive hypertension following laryngoscopy and intubation (>50 mm Hg above awake control systolic arterial pressure) compared with only 1 untreated hypertensive patient. Three of these four treated patients were well controlled and almost normotensive as a result of treatment, and there were no obvious explanations as to why they should produce such a marked sympathetic response to intubation.

Disorders of cardiac rhythm.

Many of the patients in both treated and untreated groups had disorders of cardiac rhythm during the awake control period, usually premature ventricular contractions. The incidence was higher in the untreated group (6 out of 13) than in the treated group (2 out of 16) ($\chi^2=2.56$, n.s.), although there was no consistent relationship between the incidence of cardiac dysrhythmia in the conscious patient, and the arterial pressure. Four patients developed premature ventricular contractions during the induction of anaesthesia having previously been free from dysrhythmia, and in 4 others the incidence of dysrhythmia increased during induction.

Administration of suxamethonium was not associated with the onset of dysrhythmia in any patient, but was associated with the cessation of pre-existing dysrhythmia in 8 patients (6 untreated and 2 treated).

and tracheal intubation were associated with a high incidence of dysrhythmia, usually premature ventricular contractions or ventricular bigeminy (fig. 2). These dysrhythmias occurred in 6 out of 13 untreated patients, and 5 out of 16 treated patients, and in every case they followed the onset of tachycardia and hypertension. In only 1 patient of the 44 hypertensive patients studied to date have we observed a bradycardia in response to laryngoscopy and intubation (fig. 3). One patient, a 65-year-old untreated hypertensive lady (195/80 mm Hg awake), developed wandering pacemaker shortly after induction with methohexitone 100 mg, together with occasional premature ventricular contractions, but immediately after laryngoscopy she developed ventricular tachycardia for a period of 10 seconds followed by further premature ventricular contractions.

Quantification of the changing incidence of dysrhythmia in patients with pre-existing dysrhythmia presents more difficulty than the quantification and statistical analysis of those arising de novo. We have applied cumulative sum (cusums) procedures (Woodward and Goldsmith, 1964) to identify statistically significant changes in the incidence of dysrhythmias associated with clinical events (fig. 4). Since these procedures are not widely known and used in the medical field, details of their application, and the manner in which the results are presented, the "Manhattan diagram", are described in brief in an appendix to this paper.

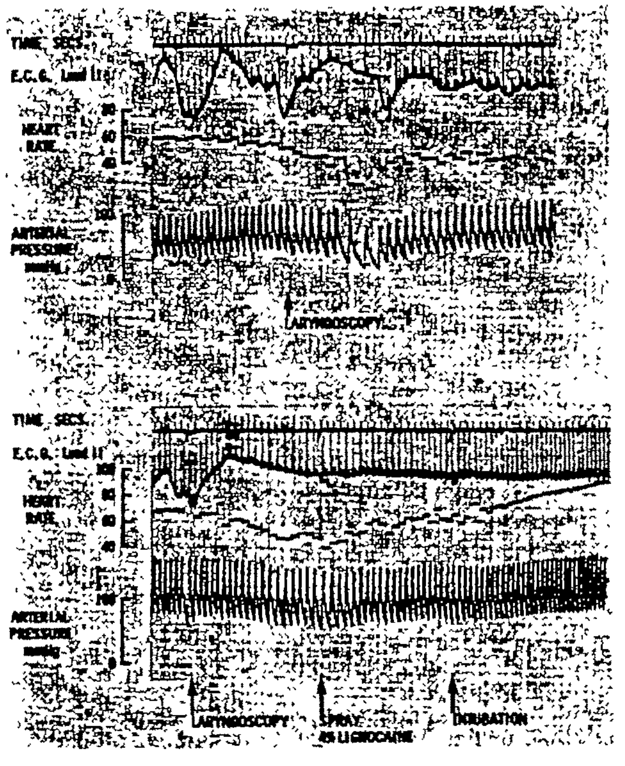

FIG. 3

Vagal reflex response to laryngoscopy. The upper panel shows the development of marked bradycardia shortly after introduction of the laryngoscope in patient No. 27 who had not previously received atropine. Following atropine 0.6 mg (lower panel), the initial heart rate was higher, but laryngoscopy still produced a bradycardia of slightly less severity before the sympathetic responses appeared.

Effect of blind nasotracheal intubation.

In 4 patients, nasotracheal intubation after inhalation of 10 per cent carbon dixoide caused no significant increase in systolic or mean arterial pressure, nor of heart rate. In 2 of these patients, previous laryngoscopy had produced a marked hypertensive response.

DISCUSSION

Our previous communication (Prys-Roberts, Meloche and Foëx, 1971) concluded that untreated high arterial pressures constituted a serious risk to patients undergoing anaesthesia and surgery. This conclusion was based on our finding of a high incidence of evidence of myocardial ischaemia related to arterial hypotension during steady-state anaesthesia in both treated and untreated patients. The results of the present study serve to emphasize that hypertensive patients are as much if not more at risk during induction of anaesthesia, and during subsequent laryngoscopy and tracheal intubation, as they are during steady-state anaesthesia. It is difficult to compare the relative risk of hypotension with myocardial ischaemia during established anaesthesia, with the excessive swing from hypertension in the conscious state to sudden hypotension during induction, followed by excessive hypertension during and after laryngeal stimulation. It is clear that these responses are not consequent upon the drugs used to manage patients with high blood pressure, but are to some extent related to the initial blood pressure. Following our findings during steady-state anaesthesia, it was surprising to find that patients on anti-hypertensive therapy with well controlled blood pressures, were equally prone to develop a hypertensive response to

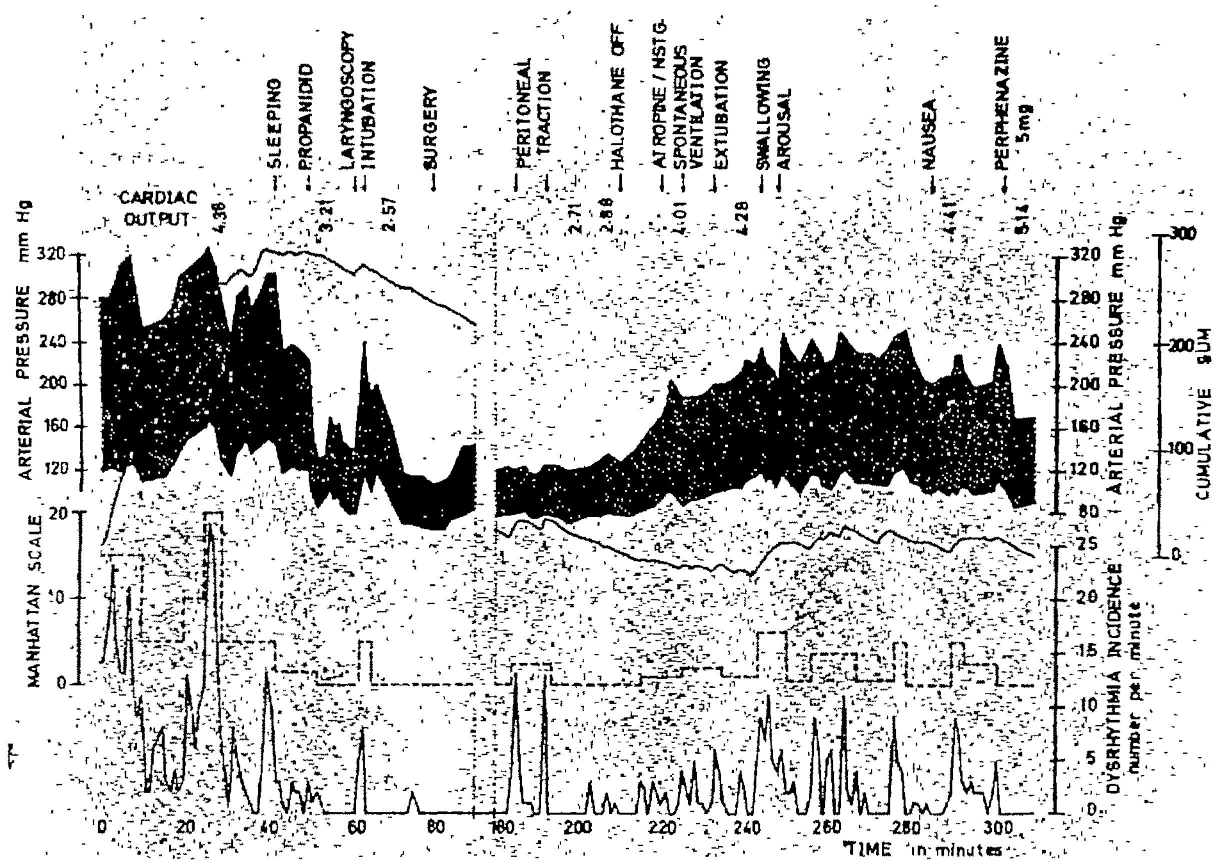

FIG. 4

Interrelation of arterial pressure and the incidence of cardiac dysrhythmia in patient No. 35. The lowest graph (continuous line) indicates the incidence of dysrhythmia, interpreted as the number of abnormal e.c.g. complexes per minute. The upper continuous line represents the cumulative sum (cusum) of this dysrhythmia incidence, and the intermediate dotted-line graph is the Manhattan diagram representing the changes in slope of the cusum graph, assessed at an arbitrary 5 per cent significance level. Assessment at the more critical 1 and 0.1 per cent significance levels showed changes to occur at the same points, but the "corners" of the Manhattan graph, representing the time of onset of a significant change in the cusum, were less obvious and of smaller magnitude.

During the pre-anaesthetic control period, the highest incidence of dysrhythmia was related to the highest arterial pressure levels which varied in a random manner, and were not associated with recognizable events. At the first event marked "sleeping", the patient fell into a natural sleep at the end of the control measurements of pulmonary gas exchange, and a significant reduction occurred in both the arterial pressure and the incidence of dysrhythmia. Although the patient could not be aroused by normal spoken command at this stage, anaesthesia was induced with propanidid in the usual way, and this event was associated with a further significant reduction of both arterial pressure and the incidence of dysrhythmia. Laryngoscopy and intubation caused a significant increase in both variables. During surgery, a 90-minute period of the record is not shown since no dysrhythmia occurred, which accounts for the progressive decline of the cusum value between the start and finish of the period. At the end of surgery, traction on the peritoneum of the pelvic floor, and of the peritoneal edges of the abdominal wall during closure, caused reflex increases in arterial pressure associated with the reappearance of dysrhythmia. Extubation, tracheal suction, and the period of arousal were associated with a progressive increase in arterial pressure and the incidence of dysrhythmia, with coincident peaks in both variables.

Cardiac output values are in l./min.

intubation, even though they were less likely to suffer drastic reduction of arterial pressure during induction.

Circulatory responses to laryngoscopy and tracheal intubation.

Reflex cardiovascular responses to mechanical stimulation of the upper respiratory tract have been described in cats (Tomori and Widdicombe 1969) and to the aspiration of secretions from the trachea in patients with normal cardiovascular reflexes (Corbett, Kerr and Prys-Roberts, 1969) and in patients with exaggerated cardiovascular reflexes due to autonomic overactivity (Corbett et al., 1969). The predominant response in man is a tachycardia and arterial hypertension, the latter being due to increased cardiac output rather than increased systemic vascular resistance, and is associated with a transient rise in the central venous pressure (Corbett et al., 1969). That these reflex responses are mediated by increased sympathetic nervous activity is based on circumstantial evidence in man, but is supported by the findings of Tomori and Widdicombe (1969) in the cat. They observed that mechanical stimulation of four areas of the upper respiratory tract, the nose, the epipharynx, the laryngopharynx and the tracheobronchial tree, induced reflex cardiovascular responses associated with enhanced neuronal activity in the cervical sympathetic efferent fibres. These cardiovascular responses, tachycardia and hypertension, and the enhanced neuronal activity were most pronounced during stimulation of the epipharynx, whereas those arising from stimulation of the tracheobronchial tree were least marked. In the present study, attempts were made to differentiate between the effects of laryngoscopy and those of tracheal intubation, and it was clear that the majority of the patients studied by us produced a reflex tachycardia and hypertension well before the act of intubation, though the effect was often enhanced by either spraying the larynx, or by intubation. Once the endotracheal tube was in position, and the laryngoscope withdrawn, the hypertension and tachycardia quickly subsided, but disturbing dysrhythmia tended to persist for up to 2 or 3 minutes. In the hypertensive patient, the extent of these cardiovascular reflexes is much more marked than in the normotensive patient.

Of the studies in normotensive man during anaesthesia, those of King and his colleagues (1951), Colon-Yordan, Mackrell and Stone (1953) and Wycoff (1960) were based on continuous records of intra-arterial pressure. Their findings were similar to ours, although the magnitude of the changes was much smaller. The study of King and associates included some patients who were hypertensive before intubation during maintenance anaesthesia with cyclopropane or diethyl ether, but they gave no indication as to whether these patients were known to be hypertensive before anaesthesia. During deep anaesthesia with cyclopropane or diethyl-ether, King and his colleagues found that the cardiovascular responses of these patients to laryngoscopy and intubation were effectively suppressed, while Colon-Yordan, Mackrell and Stone found a significant incidence (33 per cent) of ventricular dysrhythmia during intubation under deep cyclopropane-ether anaesthesia. Wycoff (1960) compared laryngoscopy and tracheal intubation under general anaesthesia with the same procedure under surface analgesia produced by cricothyroid block, and although the latter technique produced smaller changes in both blood pressure and heart rate, a sympathetic response was still present. Wycoff attributed this to soft tissue pressure by the laryngoscope (Macintosh), and also concluded that premedication with a belladonna derivative did not alter its incidence.

Takeshima, Noda and Higaki (1964) compared the effects of laryngoscopy with different laryngoscope blades, and concluded that the Macintosh blade which compressed the soft tissues of the anterior epipharynx produced a significantly greater hypertensive response than the straight-bladed Wis-Foregger laryngoscope. Simpler studies of young normotensive subjects (Takeshima, Noda and Higaki, 1964; Forbes and Dally, 1970) have established that the mean increase in arterial pressure due to laryngoscopy and intubation was of the order of 20–25 mm Hg, with maximum changes of about 40–45 mm Hg in a few subjects. In a group of normotensive patients with mitral stenosis or constrictive pericarditis, Dottori, Löf and Ygge (1970) observed significant hypertension in response to laryngoscopy and intubation following induction with nitrous oxide/oxygen/muscle relaxant (m.a.p. increased 40 per cent above conscious level), thiopentone/nitrous oxide/oxygen/relaxant (m.a.p. increased 57 per cent), and hexobarbitone/nitrous oxide/oxygen/relaxant (m.a.p. increased 18 per cent). Sinus tachycardia occurred in all patients, but was most marked in patients receiving thiopentone, and least marked following induction with nitrous oxide alone.

Hypertensive patients, whether treated or not, are prone to much greater changes in arterial pressure than normotensive patients of the same age. Dingle (1966) in a series of 19 hypertensive patients, found a mean increase in systolic arterial pressure of 35 mm Hg, with excessive increases in a few patients, but gave no details of the resting values, nor of the induction and maintenance techniques he used. The excessive swings of arterial pressure in some of our patients gave rise to considerable concern, particularly since they were accompanied by electrocardiographic evidence of prolonged ischaemia (fig. 2). Neuroleptanalgesia was used in the second group of patients in the hope that under its influence the hypertensive response to laryngoscopy would be attenuated, and that less circulatory depression would occur during maintenance anaesthesia. The lack of stability during laryngoscopy with this method was surprising in view of the cardiovascular stability which is commonly associated with NLA during surgery. However, the percentage increase in arterial pressure following NLA induction was less than with the other agents, and the different character of the arterial hypotension implies a lesser degree of myocardial depression and a decreased resistance to left ventricular ejection. These characteristics commend the technique for the induction of anaesthesia in hypertensive patients, but further measures to prevent the occurrence of severe hypertensive crises during intubation would seem to be necessary. Although the use of deep anaesthesia may suffice in the normotensive patient, our previous findings would strongly suggest that the associated hypotension and myocardial ischaemia would be undesirable in the hypertensive patient. It must be remembered, too, that in all our patients the hypertensive response to laryngoscopy and intubation occurred despite the prior establishment of a steady-state of maintenance anaesthesia with 1 per cent halothane.

Since the hypertensive response is due to increased activity in the cardiac sympathetic nerves (Tomori and Widdicombe, 1969) in the cat, and the pattern of their cardiovascular findings was almost identical with ours, it seems rational to block these responses by using a specific beta-adrenergic blocking agent. Propranolol has proved extremely effective in suppressing the hypotension, tachycardia and dysrhythmias associated with patients with sympathetic over-activity in severe tetanus (Prys-Roberts et al., 1969). In these patients, the exaggerated circulatory response to tracheal and nasopharyngeal suction of secretions was effectively suppressed by small doses of propranolol. The main disadvantage attending the intravenous use of propranolol is its quinidine-like effect of myocardial depression (Fitzgerald, 1970), although this has not been a problem in the management of patients with severe tetanus when smaller doses (0.1–0.2 mg) have been given incrementally. Propranolol and other beta-adrenergic blockers have been widely used and advocated for the management of hypertension (Gillam and Prichard, 1964; Richards, 1966; Frohlich, Tarazi and Dustan, 1969; Leishman et al., 1970), and of angina pectoris in hypertensive and normotensive subjects (Gillam and Prichard, 1965; Rabkin et al., 1966; Björntorp, 1967).

Choice of induction agent.

None of the agents used for induction of anaesthesia in this series was entirely satisfactory, although the NLA combination was less unsatisfactory than the others. Caution is required during the induction of NLA in hypertensive patients, however, and our experience with patient 21 (fig. 1) emphasizes the vascular instability of these patients, and the need for careful drug administration and continuous monitoring. We cannot agree with the recommendation of Lawin and associates (1966) that patients should be taken off antihypertensive and vasodilator drugs at least 4 days before induction of NLA. They reported three cases of cardiac arrest during induction of NLA in patients receiving vasodilator therapy. Cardiac arrest occurred within one circulation time of the rapid injection of large doses (10–22 mg) of droperidol, and although cardiac arrest was attributed to failure of cardiac filling as a result of excessive arteriolar dilatation, it is more likely to have been the result of a bolus of drug entering the coronary circulation. In our patient the onset of heart block following severe sinus bradycardia occurred 3 minutes after the end of the injection, in a patient who immediately previously had an appearance time of less than 10 seconds for a dye-dilution curve.

Propanidid was particularly vicious in its hypotensive effect which was maximal during the first minute after its administration, and before maintenance anaesthesia had been commenced. Although the steady-state arterial pressures were no lower than those following other induction agents, in view of the sudden hypotension and the marked tachycardia we cannot recommend its use in the hypertensive patient.

Contrary to the established finding that methohexitone causes less arterial hypotension in normotensive subjects than thiopentone, when used in doses comparable to this present study (Dundee and Moore, 1961), we have found that methohexitone produced a significantly greater fall in systolic and mean arterial pressure in hypertensive patients, associated with a transiently higher heart rate during the first 1–3 minutes. Although we measured cardiac output in only one of the patients receiving methohexitone (in whom no change of systemic vascular resistance occurred), our findings were otherwise similar to those of Rowlands and associates (1967) in a series of patients with pre-existing cardiac disease, all of whom had supraventricular dysrhythmias beforehand. They concluded that the moderate hypotension which occurred in their patients was almost entirely the result of a fall in cardiac output and stroke volume. It has been widely established that thiopentone causes arterial hypotension as a result of reduced cardiac output (Fieldman, Ridley and Wood, 1955; Prys-Roberts, Kelman and Greenbaum, 1967), although in normotensive subjects the rate of injection may be a significant factor (Etsten and Li, 1955). We have also measured arterial pressures by sphygmomanometry in two hypertensive patients who were induced with 10 mg and 20 mg respectively of diazepam, and in view of the marked but transient hypotension (−40 mm Hg mean arterial pressure) and the excessive hypertension following laryngoscopy in both cases (+37 and +50 per cent of the awake control values of systolic arterial pressure) we did not proceed to more complete studies. We are unable to comment as yet on the possibilities of inhalational induction for hypertensive patients, though the use of cyclopropane or halothane/nitrous oxide must be considered.

APPENDIX

Cumulative Sum procedures (Cusums)

Cumulative sum procedures (Woodward and Goldsmith, 1964) may be used to detect alterations in mean levels between groups of values in a time series, and to identify the time of onset of such alterations. The procedures are performed by a digital computer which is programmed to read in a time series, and to calculate cumulative sums of the series using the grand mean of the series as a reference value. The computer also determines the occurrence of changes in the slope of the cusum/time relation, the assessment of which is based on Student's *t*-tests, nominally applied at the 0.1, 1 and 5 per cent significance levels.

This procedure is carried out by scanning the time series in a "forward" direction in such a way as to compare each cusum value with previous significant changes in the series, and to perform *t*-tests between groups of intervening cusum values. When the *t*-test values are not significant, the computer moves to the next cusum and repeats the process. When a significant change is detected, the computer is programmed to check that the change in slope is maintained beyond the test point, and that the onset of the change (the "corner") is identified on the time scale. This scanning procedure is repeated in the reverse direction, since certain real step changes may only appear to be significant in one direction. The results of both forward and reverse scanning are then amalgamated, and the computer is programmed to print out the results in graphical form (viz. fig. 4). The Manhattan diagram, although resembling a histogram in appearance, actually represents the "corners", or points where the slope of the cusum/time relation changes significantly.

Previous applications of this method of statistical analysis in the medical field have analyzed trend changes in the mean arterial pressure in patients in whom the systolic and diastolic pressures have been varying in a random fashion around a mean level (Corbett, 1968): for example, the labile hypertension of patients with severe tetanus.

The present application enabled us to determine whether changes in the incidence of dysrhythmia as a result of induction, laryngoscopy or intubation were statistically significant events, or whether they represented random changes in the background dysrhythmia level which were due to chance.

ACKNOWLEDGEMENTS

We are grateful to Dr P. L. Goldsmith of ICI Research Department, Harrogate, for the use of the computer programme "Autocorners" (ICI/K/10881/3) used in our cumulative sum procedures. The programme was altered to our specific needs by Mrs A. Kosniowska, and was processed on the KDF9 by courtesy of the Oxford University Computing Laboratory. It is a pleasure to thank the many surgeons and physicians who have referred their hypertensive patients to us, and it is also a pleasure to thank Mr A. Ryder, Mr J. B. Thompson, Miss C. Ranson, S.R.N., Mr. P. Childs and Mr J. Aspel for their technical assistance.

The study was supported by a grant from the Medical Research Council. Dr Meloche was in receipt of a McLoughlin Travelling Fellowship (1969–70), and Dr Foëx was supported by a grant from the Hospital Cantonal et Universitaire, Geneva, and by a special grant from the Holderbank Stiftung, Aargau, Switzerland.

ETUDES DE L'ANESTHESIE PAR RAPPORT A L'HYPERTENSION

II: CONSEQUENCES HEMODYNAMIQUES DE L'INDUCTION ET DE L'INTUBATION ENDOTRACHEALE

SOMMAIRE

Les réactions électrocardiographiques et hémodynamiques à l'induction d'anesthésie, suivie de laryngoscopie et intubation endotrachéale ont été étudiées chez un groupe de seize patients hypertendus non-traités, ainsi que chez un groupe de vingt patients sous traitement antihypertenseur jusqu'au jour de l'opération inclus. Les effets de cinq agents d'induction différents, thiopentone, methohexitone, propanidid, diazepam et la neuroleptanalgésie par une association de phenoperidol et droperidol ont été comparés. La neuroleptanalgésie causa moins d'hypotension artérielle que les autres agents, mais ne procura qu'une protection marginalement meilleure contre l'hypertension, la tachycardie et la dysrhythmie, associés à la laryngoscopie et l'intubation trachéale. Propanidid et diazepam causèrent une hypotension dramatique mais passagère chez un petit nombre de patients et leur étude ne fut plus poursuivie. Methohexitone, contrairement à ses effets chez des sujets normotendus, causa chez les patients hypertendus une plus forte hypotension que thiopentone. Les auteurs donnent la rationale du bloquage prophylactique des récepteurs beta-adrénergiques pour prévenir les crises hypertensives au cours de la laryngoscopie et l'intubation, aussi bien chez les hypertendus traités que non-traités.

UNTERSUCHUNGEN ZUR FRAGE ANAESTHESIE UND HYPERTENSION

II: HÄMODYNAMISCHE FOLGEERSCHEINUNGEN VON NARKOSE-EINLEITUNG UND ENDOTRACHEALER INTUBATION

ZUSAMMENFASSUNG

Elektrokardiographische und hämodynamische Reaktionen unter der Narkoseeinleitung mit anschließender Laryngoskopie und endotrachealer Intubation wurden bei einer Gruppe von 16 unbehandelten Patienten mit erhöhtem Blutdruck und einer Gruppe von 20 Patienten unter einer antihypertensiven Therapie vor der Operation bis einschließlich dem Operationstag untersucht. Der Einfluß von 5 verschiedenen Medikamenten für die Narkoseeinleitung—Thiopenton, Methohexitan, Propanidid, Diazepam, sowie von Neuroleptanalgesie durch Kombination von Phenoperidin und Droperidol — wurde verglichen. Die Neuroleptanalgesie verursachte eine geringen arterielle Hypotesion als alle anderen Mittel, bot jedoch nur einen wenig besseren Schutz gegen Hypertension, Tachykardie und Dysrhythmie bei der Laryngoskopie und Trachealintubation als die anderen Mittel. Sowohl Propanidid als Diazepam verursachten eine dramatische, jedoch transitorische Hypotension bei einer kleinen Zahl von Patienten und wurden nicht weiter untersucht. Im Gegensatz zu ihren Wirkungen auf Personen mit normalen Blutdruck war die Blutdrucksenkung bei hypertensiven Patienten bei Methohexitan stärker als bei Thiopenton. Die theoretische Grundlage für eine prophylaktische Blockade der Beta-adrenergischen Rezeptoren zur Vermeidung von hypertensiven Krisen während der Laryngoskopie und Intubation bei behandelten und unbehandelten Hochdruckpatienten wird dargelegt.

ESTUDIOS SOBRE LA ANESTESIA EN RELACION CON LA HIPERTENSION

II: CONSECUENCIAS HEMODINAMICAS DE LA INDUCCION E INTUBACION ENDOTRAQUEAL

RESUMEN

Las respuestas electrocardiográficas y hemodinámicas a la inducción de la anestesia seguida por laringoscopia e intubación endotraqueal han sido estudiadas en un grupo de dieciséis pacientes hipertensos sin tratamiento y en un grupo de veinte pacientes bajo terapia antihipertensora hasta e incluyendo el día de la operación. Fue comparada la influencia de cinco agentes de inducción diferentes, tiopentona, metohexitona, propanidid, diacepam, y neuroleptanalgesia inducida por una combinación de fenoperidina y droperidol. La neuroleptanalgesia causó menos hipotensión arterial que cualquiera de los otros agentes, pero dio una protección sólo ligeramente superior a la de los otros agentes contra hipertensión, taquicardia y disritmia asociadas con la laringoscopia e intubación traqueal. El propanidid y diacepam causaron hipotensión dramática pero transitoria en un pequeño número de pacientes y no fueron investigados más. En oposición a sus efectos en sujetos normotensos,, a methohexitona causó mayor hipotensión que la tiopentona en pacientes hipertensos. Se explica el fundamento para un bloqueo profiláctico de los receptores beta-adrenérgicos para impedir crisis hipertensivas durante la laringoscopia e intubación en pacientes hipertensos con y sin tratamiento.

NOTICE

It is proposed to establish a Zambian Society of Anaesthetists with the ultimate object of forming a Regional Society. The inaugural meeting took place on May 29, 1971, in the Medical School of the University of Zambia at Lusaka. Any anaesthetist in Central or East Africa who is interested in supporting this venture should contact Dr F. F. Casale, F.F.A.R.C.S., University Teaching Hospital, Private Bag R. W. 1, Lusaka, Zambia, for further information.

British Journal of Anaesthesia 1998; **80**: 123–128

CORRESPONDENCE

Is sevoflurane replacing halothane?

Sir,—Mostafa and Atherton describe the successful use of sevoflurane as an induction agent in three adult patients with difficult airways.[1] My practice includes anaesthesia for children with difficult airways.

I recorded some details of the first 30 such children in whom anaesthesia was induced with sevoflurane when it became available in late 1995. My method is to use 8% sevoflurane in 100% oxygen or in a 2:1 nitrous oxide–oxygen mixture delivered from a T-piece by a bare hand. Sevoflurane is discontinued when the patient loses consciousness, halothane or isoflurane being introduced.

Anaesthesia was induced in 30 children (15 boys, 15 girls). Mean age was 3.3 yr (range 1 month to 12 yr); 11 children were aged 3 months or less. The diagnoses are listed in table 1.

Table 1 Diagnoses of children with "difficult airways" who received sevoflurane for induction of anaesthesia

Cleft lip and palate	9
Laryngeal papillomata	6
Subglottic stenosis	5
Laryngeal web	2
Micrognathia	2
Tracheocutaneous fistula	2
Beckwith's syndrome	1
Choanal atresia	1
Laryngomalacia	1
Mandibular fracture	1
Total	30

Mean time to loss of consciousness was 34.1 (SD 9.23; range 21–62) s. In all of these inductions, the only untoward event was one child who coughed twice. No patient suffered breath-holding or desaturation.

My previous calculations[2] confirm Mostafa and Atherton's impression that sevoflurane is not especially expensive when used as an *induction agent*. Sevoflurane is now my routine inhalation induction agent for children with difficult or "easy" airways.

Propofol in paediatric intensive care

Sir,—I was pleased to see another rational study of propofol in a small group of children in intensive care, together with a supportive editorial.[1,2] It always seemed to me that propofol was the scapegoat for the shortcomings of paediatric intensive care practice in the UK in the late 1980s. The problem of relative lipid overloading alluded to in many of the case reports and subsequent articles may be circumvented by use of 2% propofol solution, but this was not mentioned in the current article or accompanying editorial. Surely the ethical window has re-opened to allow a properly controlled multicentre evaluation funded by the manufacturer, akin to the adult study, but preferably using the 2% solution. The FDA has recently changed its policy on paediatric studies of new drugs.[3] It was interesting that the current evaluation received an exemption from the MCA in the UK and this should encourage paediatric intensivists to collaborate to produce an ethically acceptable and scientifically sound study.

Combined spinal–extradural analgesia in labour and post-dural puncture headache

Sir,—Jenkins,[1] and Elton and May[2] have recently commented on the incidence of post-dural puncture headache (PDPH) associated with combined spinal–extradural analgesia in labour. Jenkins suggested that the use of low-dose extradural only analgesia is preferable to a combined spinal–extradural technique because of the high incidence of PDPH (2.3%) reported by Collis and colleagues.[3] Elton and May, in reply, cited the study by Norris and colleagues[4] to suggest that combined spinal–extradural analgesia in labour may not be associated with an excessive incidence of PDPH.

The combined spinal–extradural technique in obstetrics was used initially by Brownridge[5,6] for anaesthesia for elective Caesarean section. He used a dual space technique. In an uncontrolled series of 200 women undergoing this technique, there were no cases of PDPH. Brownridge attributed this fact to extradural bolus doses of pethidine which these women received for postoperative analgesia. However, this encouraged the notion that combined spinal–extradural techniques might be associated with lower PDPH rates than either technique alone.

The incidence of PDPH cited by Jenkins, namely 2.3% in the study by Collis and colleagues[3] from Queen Charlotte's Hospital, is certainly unacceptable in an obstetric regional analgesia service. However, there were particular reasons why the PDPH rate was so high in that particular study. The study was a prospective observational study of combined spinal–extradural analgesia in labour in 300 women. A single space needle-through-needle technique using 16-gauge Tuohy and 27-gauge atraumatic spinal needles was used. The inadvertent dural tap rate was 1%. There was a 10.6% failure rate in obtaining CSF with the long 27-gauge atraumatic needle. This was partly because all 300 women were in the left lateral position during insertion of the combined spinal–extradural. Norris and colleagues[4] found that they were significantly more likely to obtain CSF in the sitting than in the lateral position. Sagging of the midline skin crease and reduced hydrostatic pressure head of CSF in this position may conspire to increase the likelihood of a dry tap. Furthermore, trainees with varying levels of competence and experience in any form of obstetric regional block performed all blocks in the Queen Charlotte's Hospital study. To increase the chances of obtaining CSF, multiple deliberate dural punctures with the spinal needle were used, accounting for the excess incidence of PDPH over and above the observed inadvertent Tuohy tap rate of 1%.

As experience with the combined spinal–extradural technique increased in this unit, Morgan and Kadim[7] were able to report that in the next 1565 women who received combined spinal–extradural analgesia, inadvertent dural tap rate had decreased to 0.45% and the incidence of PDPH as a result of deliberate dural puncture with a 27-gauge atraumatic spinal needle had decreased to 0.13% from 1.3%; failure to obtain CSF occurred in only 5.3% of cases.

The study by Norris and colleagues[4] reported an apparently lower incidence of inadvertent dural puncture in women who had combined spinal–extradural analgesia rather than extradural analgesia in labour (notwithstanding that their overall inadvertent dural tap rate was 2.7%). However, that particular unit reserves extradural analgesia for later in labour and combined spinal–extradural analgesia for those who request regional analgesia earlier in labour. As distressed parturients in later labour are more likely to be moving targets than women in early labour, it is not surprising that the inadvertent dural tap rate is higher in this group. This would presumably be the case even if they received combined spinal–extradural analgesia rather than extradural only analgesia.

There is no conclusive evidence that combined spinal–extradural analgesia in labour is associated with an excessive incidence of PDPH. But it would seem preferable to restrict the use of combined spinal–extradural analgesia to those women who request regional analgesia in later labour (so as to benefit from the rapidity of onset of analgesia); those who require instrumental assisted delivery in the absence of a pre-existing regional block; and those who at any time in labour are excessively distressed (so as to rapidly achieve control of the situation).

7. Morgan BM, Kadim MY. Mobile regional analgesia in labour. *British Journal of Obstetrics and Gynaecology* 1994; 101: 839–841

Sir,—I thank Dr McLoughlin for his interest in my letter. The high rate (2.3%) of post-dural puncture headache (PDPH) in the original series of 300 combined spinal–extradurals for analgesia in labour, reported by Collis and colleagues,[1] was the only published data available when we made our decision to use low-dose extradural alone rather than combined spinal–extradural analgesia. Subsequently, Morgan and Kadim[2] reported a much lower rate of PDPH after combined spinal–extradural analgesia for labour. Recently, cases of both aseptic[3,4] and bacterial[4,5] meningitis have occurred after combined spinal–extradural analgesia in obstetrics. I believe combined spinal–extradural techniques should be used with caution for analgesia in labour.

Sir,—We agree that the evidence that combined spinal–extradural analgesia increases the incidence of post-dural puncture headache (PDPH) is conflicting. This expands the assertion in our original letter.[1] Combined spinal–extradural analgesia has proved extremely popular in centres in which it has been introduced, including Queen Charlotte's Hospital.[2] It has been suggested that conventional extradurals with bolus doses of plain bupivacaine are associated with increased operative[3] and instrumental delivery and long-term backache.[4] It is possible that combined spinal–extradural analgesia in labour has a different profile of side effects.[5]

It would be prudent to await the results of large scale, randomized controlled studies with long-term follow-up to establish the role of combined spinal–extradural analgesia in labour. We agree that where it is necessary to achieve rapid onset of profound analgesia, particularly where pain is of sacral origin, combined spinal–extradural analgesia has advantages.[6] However, the fact that anaesthetists at Queen Charlotte's Hospital experienced a greater incidence of side effects when combined spinal–extradural analgesia was introduced compared with subsequent studies[3] would imply that the use of an unfamiliar technique in such fraught situations may not be desirable.

Transposition of rotameter tubes

Sir,—With the publication of the new checklist for anaesthetic apparatus from the Association of Anaesthetists,[1] we feel that the incident reported in this letter will highlight the importance of these checks. However, in addition, having read carefully this document we can find no instruction which would ensure that the fault we describe would be detected in the future.

There were two reports of a rotameter and a bobbin swap from the USA in 1974.[2,3] However, there has previously been no report in this country of such an incident. But the morning after an anaesthetic machine service in this hospital, a full check of the anaesthetic machines in the anaesthetic room and operating theatre was made according to the guidelines of the Association of Anaesthetists of Great Britain and Ireland (AAGBI)[4] by the anaesthetist who was working in that theatre. Nothing untoward was noted at this time. Anaesthesia was carried out safely in the first patient in the anaesthetic room before transfer to theatre. As soon as the anaesthetist turned on the gas flows on the machine in the operating theatre he realized that the flowmeter above the nitrous oxide flow control valve was only calibrated to 2 litre. On closer inspection, this flowmeter was noted to be colour coded and labelled for carbon dioxide. The flowmeter above the carbon dioxide flow control valve was conversely colour coded and labelled for nitrous oxide (fig. 1). The anaesthetist administered 100% oxygen and a volatile agent to the patient while the anaesthetic machine was changed. The patient came to no harm.

How did the flowmeters get swapped? It is standard practice for the service engineer to remove, clean and replace each flowmeter in turn. On this occasion one of the flowmeters was broken on cleaning and then the next was removed, cleaned and replaced before a replacement for the broken one was found. This led to the swap.

Why was this swap not detected during the anaesthetic machine check? The checklist for anaesthetic machines[4] states to "set a flow of approximately 5 litre min^{-1}" for the flowmeters. The new trainee anaesthetist knows that this is approximately 50–66% up the oxygen and nitrous oxide flowmeter, without reading the scales. Therefore, the flowmeters were not read accurately to 5 litre during this check. Extra vigilance is needed in checking the anaesthetic machine to exclude a crossover of flowmeters after a machine service. How might such a potentially serious fault be avoided in future? Flowmeter design could be changed so that it would not be possible for them to be interchanged. Clearly the procedures being followed by the service engineer were not foolproof. Perhaps after each anaesthetic machine service the

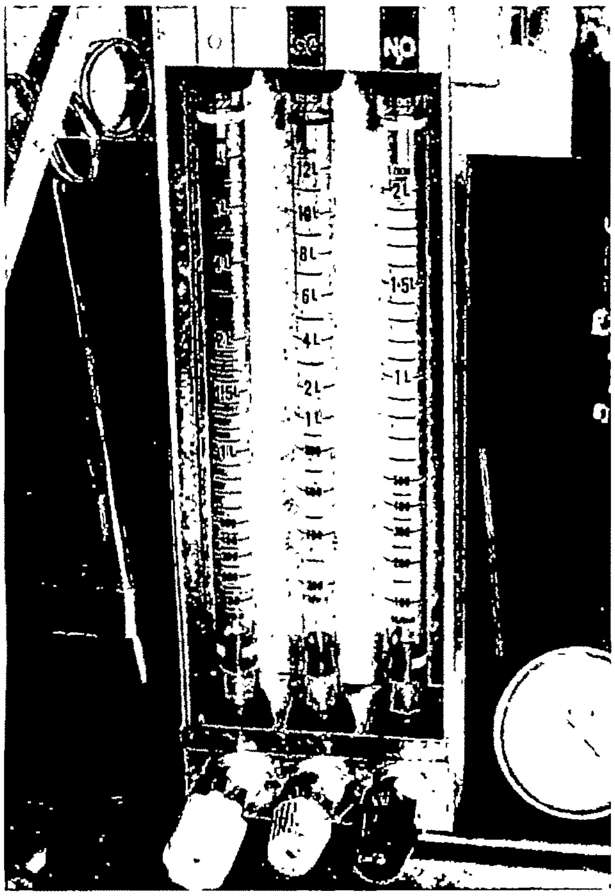

Figure 1 Flowmeters of the anaesthetic machine.

machine should be double checked by an independent technician. A much more comprehensive checklist than the one currently described by the AAGBI is possibly required after a machine service. Currently, we reinforce to our trainees that they must set the bobbin height to exactly 5 litre when doing their anaesthetic machine checks to guarantee that the flowmeter calibrations are read accurately.

The second question to be asked is what difference to the outlet gas mixture would a switch of this sort make? The two possibilities are of an hypoxic mixture (picked up by the oxygen analyser) or an oxygen-enriched gas mixture leading to the possibility of awareness. Afterwards, oxygen and nitrous oxide concentrations from the faulty machine were measured, setting both flowmeters to read 2 litre as this was the maximum the "nitrous oxide" flowmeter could read. Equal concentrations of each gas were emerging from the common gas outlet. If the flowmeters are calibrated for individual gases, why was the flow of nitrous oxide through a carbon dioxide flowmeter accurate? With the bobbin type of flowmeter, the physical property determining flow is gas viscosity at low flow rates and gas density at high flow rates. The viscosities of carbon dioxide and nitrous oxide are 13.9 and 13.5 Pa.s, respectively. The density of both is 1.98 kg m^{-3}.

In summary, although service procedures are set and followed by companies, mistakes can occur. No checklist can ever be foolproof. Extra vigilance in checking anaesthetic machines is strongly recommended, particularly after servicing. The importance of following the AAGBI checklist for anaesthetic apparatus[1] cannot be overemphasized. However, a more comprehensive checklist may be required after an anaesthetic machine service.

Effect of hydroxyethyl starch on coagulation is difficult to assess *in vitro*

Sir,—We have read with interest the *in vitro* studies carried out by Egli and colleagues on the effect of haemodilution with hydroxyethyl starch (HES), gelatin and albumin on blood coagulation.[1] However, we cannot agree completely with the conclusion that HES compromises blood coagulation more than other substances because *in vitro* studies of the effect of HES on blood coagulation are, unfortunately, of limited value.

HES leads to coagulation disorders, particularly through impairment of factor VIII/von Willebrand factor. In 1985, Stump and colleagues[2] were able to show that this effect only occurs *in vivo*, not *in vitro*. They speculated that the reason for this could be either reduced release or impairment of the synthesis of factor VIII/von Willebrand factor. Our own studies support the hypothesis that accelerated elimination of factor VIII/von Willebrand factor is the cause for the observed coagulation disorders.[3] It is difficult, therefore, to simulate through *in vitro* studies the complex interaction of HES with the clotting system and in particular elimination via the reticuloendothelial system.

These difficulties are enhanced by the fact that the chemical composition of HES changes markedly *in vivo*. In recent studies, we were able to show that HES is metabolized *in vivo* in complex ways,[4 5] and that impairment of factor VIII/von Willebrand factor depends exclusively on the *in vivo* molecular weight of HES. This explains why haemorrhagic complications have almost exclusively been observed with high and medium molecular weight HES, which is not easily metabolized by the body, resulting in high *in vivo* molecular weights of the HES molecules HES with a medium or low molecular weight which is easily metabolized does not lead to a reduction in factor VIII/von Willebrand factor beyond the dilution effect, and rarely leads to haemorrhagic complications.[6] *In vitro* studies do not take into account this new finding, because HES is not metabolized *in vitro*, resulting in unrealistically high molecular weights of the starch molecules which are not observed *in vivo*.

Nevertheless, we believe that the experimental model of Egli and colleagues is innovative and interesting, particularly as the pathological mechanism of impairment of the clotting system through HES and the mechanism of the reduction in factor VIII/von Willebrand factor have not yet been elucidated. Future *in vitro* studies that incorporate the recent results should be able to yield interesting new insights.

6. Treib J, Haass A, Pindur G. Coagulation disorders caused by hydroxyethyl starch. *Thrombosis and Haemostasis* 1997; 78: 974–983.

Sir,—Drs Grauer and Treib were concerned that the *in vitro* finding of an exaggerated effect on blood coagulation of hydroxyethyl starch (200 000/0.5) (HES) compared with gelatin and albumin solutions[1] would not be completely applicable to the *in vivo* situation. This concern was based on two findings: first, an apparent lack of a decrease of factor VIII/von Willebrand *in vitro* with impairment of blood coagulation[2]; and second, on the observation that the mean *in vivo* molecular weight of HES decreased during long-term haemodilution in the treatment of cerebrovascular disease with an associated decrease in blood coagulation.[3]

Stump and colleagues described stable VIII/von Willebrand factors in their *in vitro* experiments assessing mixtures of HES and plasma.[2] These results were achieved in citrated plasma to prevent clotting. Interestingly, when blood coagulation is not inhibited, as in our study using thrombelastography, HES and dextran solutions may precipitate coagulation factors such as factor VIII/von Willebrand *in vitro* also.[4] The effect of HES in decreasing factor VIII/von Willebrand thus would not have been missed in our *in vitro* studies. In addition, if we were only able to partially detect the effect of a decrease in factor VIII/von Willebrand in our *in vitro* study, we would have underestimated the *in vivo* difference between the blood coagulation effect of HES compared with albumin and gelatin solutions. Thus we cannot agree with the concerns of Grauer and Treib that our results would not substantiate a more exaggerated effect on blood coagulation of HES than albumin or gelatin solutions.

Treib, Haass and Pindur have recently suggested an interesting new concept to predict the effect of long-term haemodilution therapy using various types of HES on blood coagulation.[3] In patients treated for cerebrovascular disease, they found that the mean molecular weight of HES solutions decreased after infusion *in vivo* and that the effect on blood coagulation of these different HES solutions was better related to the mean *in vivo* molecular weight measured after 5–10 days than to the mean *in vitro* molecular weight (i.e. the mean molecular weight of the HES solution in the bottle before infusion).[3] During surgery, however, HES is administered for relatively short periods of time according to surgical blood loss and the volume replacement requirements of the patient. Thus additional HES solution of the original *in vitro* molecular weight is infused continually and therefore HES molecules with a molecular weight similar to *in vitro* molecular weight exert their effect on blood coagulation. The concept of the (long-term) *in vivo* molecular weight of a particular HES solution affecting blood coagulation is of limited clinical relevance for the intraoperative and early postoperative period.

In vitro testing of the effect of various volume expanders on blood coagulation using thrombelastography is considered adequate. Nevertheless, *in vitro* findings have to be confirmed *in vivo* before final conclusions regarding clinical management can be deduced.

Haemostatic changes during total knee arthroplasty with different anaesthetics

Sir,—The study by Sharrock and colleagues[1] on haemostatic changes in total knee arthroplasty with different anaesthetic techniques reflects the continuing search for a better understanding of the mechanisms of postoperative deep vein thrombosis in major joint arthroplasty. There are three comments I would like to make.

While they are partially correct in their discussion that in total hip arthroplasty we did not confirm using spinal anaesthesia Modig and colleagues' findings of suppressed fibrinolysis with extradural block,[2] this was largely a reflection of haematological methodology. There were demonstrable differences between general anaesthesia and spinal anaesthesia in some measured haemostatic variables.[3] When comparing spinal anaesthesia with general anaesthesia in the immediate perioperative period, platelet count did not increase to the same extent, thrombin generation index (a measure of activation of coagulation) and factor VIIIRAg did not increase and there was less activation of fibrinolysis (as demonstrated by euglobulin clot lysis time).

These changes were consistent with suppression of the neuroendocrine response to surgery with spinal anaesthesia, as demonstrated by changes in plasma concentrations of cortisol in our patients[4] and were similar in the general anaesthesia group to those seen with exercise and exogenous infusions of epinephrine.[5 6] In our study, no exogenous catecholamines were used and it is possible that any differences between general and extradural anaesthesia in the study of Sharrock and colleagues were hidden by the use of epinephrine in the extradural local anaesthetic solution and i.v. ephedrine for cardiovascular control.

With respect to their comments on limb blood flow, based on our impedance plethysmography study during hip arthroplasty,[7] the enhanced blood flow seen in the surgical limb after relocation of the prosthesis and into the postoperative period with spinal anaesthesia compared with general anaesthesia may not necessarily apply to knee arthroplasty. In the latter case, maximal vasodilatation would be expected in the exsanguinated limb after tourniquet release, at least initially, irrespective of the anaesthetic technique used. It will be difficult to follow through this hypothesis with flow studies on patients undergoing knee arthroplasty.

Given the New York group's very large clinical experience in knee arthroplasty, I would be interested in their views on correct exsanguination of the limb before tourniquet inflation and its importance for the occurrence of deep vein thrombosis. Not all orthopaedic surgeons use a compression Esmarch bandage, and when they do so it is not always applied efficiently. This could well influence coagulation–fibrinolysis changes in the surgical limb.

7. Davis FM, Laurenson VG, Gillespie WJ, Foate J, Seagar AD. Leg blood flow during total hip replacement under spinal or general anaesthesia. *Anaesthesia and Intensive Care* 1989; 17: 136–142.

Sir,—We appreciate Dr Davis' comments on our article, as he was perhaps the first person to highlight the role of regional anaesthesia in the genesis of venous thrombosis.[1]

The first question relates to his observation of increased thrombin generation during operation and decreased fibrinolysis after operation in patients receiving general anaesthesia during total hip replacement (THR).[2] We noted no increase in thrombin generation (measured by thrombin–antithrombin complexes) or in the effect of thrombin formed (fibrinopeptide A), nor did we note any difference in fibrinolysis, although our study did not extend into the postoperative period. These differences most likely reflect the different operations and possibly the differences in blood loss between spinal and general anaesthesia during THR. There is no effect of anaesthetic technique on blood loss with total knee replacement (TKR).

The issue of the use of catecholamines during anaesthesia is an important point. Although epinephrine and exercise increase fibrinolysis in young people, we were unable to detect any augmentation during THR in elderly patients.[3] In contrast, we have noted that infusions of epinephrine are associated with less thrombogenicity during TKR performed with a tourniquet.[4] These are preliminary observations and whether or not this represents a suppressant effect of epinephrine on coagulation or a vascular effect is unclear.

With a tourniquet, there is little opportunity for extradural anaesthesia to augment flow in the operative limb and thereby alter venous thrombotic tendencies This was one of the reasons we chose to study TKR, as flow should not be a confounding variable. As we were unable to see any difference in fibrinolysis or markers of thrombin generation in our patients, we hypothesized that augmentation of flow after surgery may account for the decreased rate of deep vein thrombosis (DVT) noted with extradural anaesthesia after TKR. Whether or not this is true is unknown.

The final point relates to how well the leg is exsanguinated before tourniquet inflation. I suspect this is a significant determinant of the degree of venous thrombosis. Any blood remaining in the leg will be static and a potential nidus for DVT. For this reason, our surgeons assiduously attempt to exsanguinate the leg with an Esmarch bandage before inflating the tourniquet. However, to the best of my knowledge, this has not been studied.

I thank Dr Davis for his comments, as a fuller understanding of factors contributing to intraoperative thrombosis will help reduce morbidity after surgery.

Extradural anaesthesia in elective Caesarean section

Sir,—We read with interest the article by Morton and colleagues[1] and would like to raise several points. First, we were concerned that the results of nine women from a study containing only 38 women were not valid for analysis of efficacy or pharmacokinetics, or both. This is a drop out rate of approximately 25%. Second, one patient who apparently had sensory block to T6 after receiving 0.75% ropivacaine 20 ml and increments of 2% lidocaine had spinal anaesthesia for Caesarean section because surgery was delayed. Analysis of table 3 shows that in this patient, surgery started 114 min after extradural injection. Analysis of table 2 shows that the median duration of sensory block at T6 was 3.4 h (range 1.3–5.8 h). Although the results of this patient were not included in table 2, this patient should still have had a significant sensory block. Why was this patient then given a spinal anaesthetic? If the height of the sensory block had receded it could easily have been extended by injecting more local anaesthetic via the extradural catheter. Furthermore, there are several reports in the literature where very high or total spinal blocks have occurred when spinal anaesthesia has been performed after extradural anaesthesia.[2-4]

Third, two mothers received accidental i.v. injection of ropivacaine 75 mg and 150 mg, respectively. The second of these patients developed mild signs of i.v. injection after a dose of 75 mg but symptoms resolved, and therefore the authors gave another 75 mg at which time the symptoms recurred. Surely the authors should have stopped injecting after the initial 75 mg, aspirated the extradural catheter and waited a few minutes to see if any signs of sympathetic, sensory or motor block developed. If no signs of extradural block had developed the catheter should have been assumed to have been placed i.v. Furthermore, were there any signs of i.v. catheterization at the time of siting and were the catheters aspirated before injecting the test dose? It is fortunate that the study was not double-blind with bupivacaine!

Fourth, the authors failed to mention which form of anaesthetic was administered to the mother who received ropivacaine 150 mg i.v. The authors did not give the results of neonatal outcome in the two mothers who had accidental i.v. injection. Were their NACS scores normal?

Finally, as the authors mentioned in their discussion, the open design of the study had limitations, namely it prevented true comparisons with other agents or even with 0.5% ropivacaine. The conclusions of the study were somewhat predictable in that 0.75% ropivacaine should provide better analgesia compared with 0.5% ropivacaine or bupivacaine.[5] However, what is interesting is that 21 of 31 neonates in this study had a 2-h NACS score of less than 35 while in the study of Griffin and Reynolds,[5] where 0.5% ropivacaine was used, only five of 31 neonates had a 2-h NACS score of less than 35.

4. Stone PA, Thorburn JA, Lamb KSR. Complications of spinal anaesthesia following extradural block for Caesarean section. *British Journal of Anaesthesia* 1989; 62: 335–337.
5. Griffin RP, Reynolds F. Extradural anaesthesia for Caesarean section: double blind comparison of 0.5% ropivacaine with 0.5% bupivacaine. *British Journal of Anaesthesia* 1995; 74. 512–516.

Sir,—We thank Drs Patel and Baxter for their interest in our article. The reasons for the results from seven women being invalid for efficacy analysis were technical difficulty in siting the extradural catheter or failure to establish sensory block. Blood samples from another two women (with satisfactory extradural blocks) were not available for analysis for reasons stated in the article. Many authors do not report the fate of patients who are excluded from a study after recruitment (i.e. after giving informed consent) but we believe it is good scientific practice to do so. Furthermore, because ropivacaine was then an unlicensed drug, we felt it important to report the results from all patients who received it, including four of the above seven patients.

Drs Patel and Baxter question our choice of subarachnoid anaesthesia for the woman whose Caesarean section was delayed, inferring from the pooled data that she should either have had adequate block or block could have been extended. First, a median duration of sensory block at T6 of 3.4 h does not imply that this patient's block would have been adequate at the time of surgery. Second, we do not agree that her block could have easily been extended. The reason that she had received additional local anaesthetic was because of inadequate block. In addition, we were concerned about the possibility of systemic local anaesthetic toxicity. We are aware of the reports of high block when subarachnoid anaesthesia is used after inadequate extradural block but felt that the balance of risks still favoured this technique.

The second of the two mothers who received accidental i.v. injections of ropivacaine underwent Caesarean section under subarachnoid block. She received 0.75% ropivacaine 20 ml because her symptoms (not signs) were inconclusive. The injection was given slowly, which we believe is vital for safety, and therefore even if bupivacaine had been used, warning symptoms should have occurred before serious systemic toxicity developed. All extradural catheters were placed and all clinical decisions made by the consultant in charge of the patient's anaesthetic care. This person was not the investigator. As stated in the article, all catheters were aspirated.

NAC scores at 2 h and 24 h for the two women who received accidental i.v. injections were 30, 31 and 33, 36, respectively. None of the neonates in the study gave clinical cause for concern except that, as discussed in the article, one developed transient tachypnoea of the newborn.

The expanding role of simulators in risk management

Sir,—We read with interest the recent correspondence by Dr Byrne and Professor Jones[1] in response to Professor Spences' editorial[2] on the expanding role of simulators in risk management. We are also aware of the excellent work that is being done with the ACCESS simulator.

We admit that we are fortunate in Bristol to have acquired one of the two commercially available American high-fidelity simulators. The METI version that we purchased cost approximately $200 000. The rest of the project money was used to house the simulator in a purpose-built education centre with additional computer-assisted learning (CAL) and conference facilities. The METI high-fidelity simulator can be used by single-handed operators for individual or group tutorial style teaching. It can also be used for the more glamorous scenario-based "anaesthesia crisis resource management" training. It is true that this type of training is time consuming, requires many trainers and benefits only a few trainees at a time.

In Bristol, we are encouraging the involvement of committed medical teachers (not just anaesthetists) to use our centre. Medical students and trainee anaesthetists attend the centre for tuition on a regular basis. Geographical location does mean that those in the South West of England are more likely to benefit from informal teaching programmes but we hope the commercial courses will appeal to many around the country. The manikin is immobile at present but it is our intent that teaching and training by simulation be available to a wider audience in the future. Pilot projects in the USA involve moving the simulator from one hospital base to another. This is potentially damaging to expensive equipment but mobile units may be available in the future. Alternatively, telemedicine links may provide opportunities for simulation teaching to a wider audience.

If high-fidelity simulators are to be used for trainee assessment and continuing medical education in the future, several points need to be considered. First, access to simulator facilities will need to be readily available. Second, trainers using simulators will need to cooperate and develop teaching and assessment programmes together, and third, the benefits of simulation as a teaching tool or in improving clinical performance need to be validated.

We are sure that the future success and developments of simulation lies in the collaborative efforts of those working in this exciting field of education.

BOOK REVIEWS

Anesthesia for Aortic Surgery. J. I. Simpson (editor). Published by Butterworth–Heineman, Oxford. Pp. 394; indexed; illustrated. Price £55.00.

This book attempts to bring together, in a single volume, anaesthesia for those aortic procedures normally covered by a range of different subspecialties, such as cardiac, thoracic, paediatric and vascular surgery. The 21 contributing authors work in US centres, with one exception. The book is comprised of 13 chapters covering preoperative, intraoperative and postoperative care of these patients. There is some overlap, mainly with some of the anatomical discussions, with classification of aneurysms and with monitoring.

The first five chapters cover anatomy, preoperative risk assessment, radiological evaluation, monitoring, and bleeding and transfusion. Preoperative risk assessment covers predominantly coronary artery disease, but pulmonary and renal disease together with hypertension and diabetes are also included. With respect to haemodynamic optimization, the discussion is more typical of American practice, particularly the assumption that preoperative intensive care is available. However, the authors admit that its value is disputed. The chapter on radiological evaluation is informative and, as one would expect, well illustrated.

I particularly enjoyed the section on monitoring. It included discussion of the advantages and disadvantages of transoesophageal echocardiography in detecting wall motion abnormalities and the use of pulmonary artery catheters to monitor ischaemia and filling pressures. The discussion on measurement of cardiac contractility makes excellent reading. There is also an important discussion on the relative merits of central venous pressure monitoring compared with pulmonary artery catheter monitoring. This chapter also includes consideration of monitoring of brain and spinal cord function, with excellent contributions on the use of somatosensory evoked potentials and motor evoked potentials. The role of the EEG in deep hypothermic circulatory arrest is also included.

The middle chapters of the book cover the specifics of particular surgical procedures, divided into the ascending arch and descending aorta, together with chapters on anaesthesia for coarctation and the abdominal aorta. All of these chapters make good reading. Where appropriate they include sections on presentation, cerebral protection (including retrograde cerebral perfusion and the use and effects of hypothermia), alpha stat compared with pH stat management of arterial blood-gas tensions, and prevention of spinal cord ischaemia (including selective spinal cord cooling).

The latter part of this book covers postoperative care. Cardiopulmonary care is particularly well discussed, although I felt that perhaps there was too much discussion on the benefits or otherwise of "supranormal" oxygen delivery. However, many recent and highly relevant references are included. This section also included comment on the transfer of patients from the operating theatre to the intensive care unit, an area which sadly is often overlooked.

An entire chapter is devoted to the postoperative care of other "end organs", and including the central nervous system, renal function, coagulation and transfusion, and the gastrointestinal system. The latter discussion is particularly good but is marred by a poorly reproduced figure. The final chapter is devoted to discussion of postoperative management of pain in the aortic surgery patient. This is an excellent chapter and in many respects could equally apply to many other branches of surgery. It covers the available techniques and the use of different opioid analgesics by different routes. However, diamorphine is not included in this discussion.

This book has a comprehensive index and is well referenced. Inevitably, however, very few of the references are later than 1994. The tables, photographs and figures are, with one or two exceptions, usually of a high standard.

Overall I enjoyed this book. However, there were some problems. Naturally American drug names are used but I do find it irritating that throughout, where American units of measurement are used there are no SI equivalent values given. This applies both in the tables and text. Most British readers will not have a problem with electrolytes expressed in milli-equivalents, but expression of creatinine, for example, in imperial units will probably be unfathomable! There was one other infringement which this reviewer found particularly disconcerting! The name of the Liverpool based guru of paediatric anaesthesia, Jackson Rees, was spelt incorrectly.

These criticisms aside, the true test of this book will be to see who buys it. I suspect that those post-fellowship trainees considering a career in the relevant specialties may find this book attractive. Whether or not they will be prepared to spend £55, remains to be seen.

R. Wenstone

Head Injury Pathophysiology and Management of Severe Closed Injury. P. Reilly and R. Bullock (editors). Published by Chapman and Hall Medical, London. Pp. 478; indexed; illustrated.

This textbook has 27 authors and two editors from Australia, the USA and the UK. Twenty-nine chapters form three sections: the injury, measuring and monitoring injury and treatment. There are many figures and well reproduced images of CT and MRI scans, with some colour illustrations of newer imaging methods. Mixing of experts from different continents works well and the sources and perspectives are truly international and avoid the parochialism so common in US textbooks. Throughout the text certain key phrases, or sentences, are marked in bold italics. Some readers may find this irritating but I found it helpful and appreciated having important points emphasized. The breadth of the text is ambitious, covering air bags to excitatory amino acids. This is not just a tome on how to manage head injuries, it also informs on who suffers from them, how we might prevent them, processes taking place in the brain and how these might be detected and modified. The index is comprehensive; I looked up neuromuscular blocking agents, ketamine, hypothermia and hyperbaric oxygen and found useful information on all of them.

New drug treatments for head injury are eagerly awaited by clinicians and these are well reviewed in a chapter on "Neuroprotection in head injury" with many recent references. The balance of topics within individual chapters reflects the authors' interests. The section on patient transfer deals exhaustively with aeromedical evacuation and only briefly mentions road ambulances. Nevertheless the key points are covered.

The chapter on outcome dealt thoroughly with the controversies surrounding testing for brain stem death and the differences between US and UK practice. However, to be useful as a reference for trainees learning how to do the tests, some illustrations and explanations of the pathways involved would also have been appropriate. The persistent vegetative state is also well covered.

I liked this book because it is well written and interesting. I strongly recommend it to departmental libraries and interested individuals.

EDITORIAL

Death in the dental chair: an avoidable catastrophe?

At present approximately 300 000 patients undergo general anaesthesia for minor dental procedures in the UK each year. Of these 300 000, approximately 2 die.[1] Anaesthesia most commonly consists of a mixture of oxygen, nitrous oxide and halothane and is administered in general dental practices, community dental surgeries and hospitals. Of the 26 patients who died in the course of a dental anaesthetic between 1984–1993 (information from the British Dental Association) more than 50% were children less than 16 yr of age. A previous mortality report[2] suggested that the precipitating causes were distributed equally between respiratory difficulty and sudden cardiovascular collapse. Recent data obtained from the coroners' reports of two patients in the latter group suggest that the typical course of events is that they suffer an unexpected cardiac arrest with no obvious precipitating factor. The cardiac arrest in both cases proved resistant to resuscitative measures and the post mortems did not provide evidence as to the cause of the cardiac arrest and the deaths went unexplained.

It has long been known that patients undergoing general anaesthesia for dental procedures suffer changes in heart rhythm.[3–6] Stimulation of the sympathoadrenal system via the fifth cranial nerve in the presence of halothane is considered to be a major factor in the production of these arrhythmias. Halothane is also known to slow conduction between the atria and bundles of His and slow conduction in the ventricles. It has been postulated that this mechanism may allow re-entrant activity[6] and hence produce arrhythmias. The incidence of arrhythmias in dental surgical patients anaesthetized with halothane varies between 18% and 75%. Ryder and Wright[4] compared the use of halothane and enflurane in dental anaesthesia and showed that the incidence of arrhythmias with halothane was 32%, whereas it was only 9.8% with enflurane. Cattermole and colleagues[5] compared isoflurane with halothane and found that the incidence of arrhythmias with isoflurane was only 14%, which was 38% lower than with halothane.

The nature of the arrhythmias differed depending on the volatile agent used; with enflurane and isoflurane there was a total absence of ventricular ectopic beats whereas with halothane they occurred frequently. Ventricular arrhythmias are generally thought to carry a higher risk than those that are supraventricular in origin as the former are more likely to progress to ventricular fibrillation.[7] However, halothane has remained the agent of choice for inhalation induction and maintenance of anaesthesia in dental patients as both enflurane and isoflurane are irritant and can cause excessive coughing, salivation and laryngospasm.

Several large scale studies[8–11] revealed that the commonest causes of cardiac arrest during anaesthesia are hypoxia as a result of ventilatory problems and "overdose" of anaesthetic agent, particularly when combined with hypovolaemia, post-induction hypotension and post-succinylcholine asystole. In most cases of cardiovascular collapse, patients had pre-existing disease and were undergoing major surgery. This contrasts sharply with dental out-patients who are healthy individuals undergoing relatively minor surgery where cardiac arrests have occurred without any obvious precipitating factor. The nature of the arrests in the children who died was also unusual. Paediatric cardiac arrests are characteristically asystolic,[12] whereas children having dental treatment who are anaesthetized using halothane are prone to ventricular arrhythmias,[3 4] some of which have proceeded to ventricular tachycardia. In one case described in the coroner's court, ventricular fibrillation occurred without any preceding change in normal rhythm. Unfortunately data on the incidence of cardiac arrest during anaesthesia for dental surgery are limited as only deaths are recorded.

The number of deaths associated with dental anaesthesia is decreasing. The first Coplans and Curson report[2] examined deaths in dentistry over the decade 1970–1979, and during this period more than 15 million anaesthetics were given with a total of 100 deaths. In the period 1980–1989, the number of deaths had decreased to 42.[13] However, it is suggested that the reduction in mortality was attributable largely to the decrease in the number of general anaesthetics administered rather than improved standards, although no information is available on the numbers of general anaesthetics given during this latter period.

Nevertheless, because of the ongoing mortality (another two highly publicized deaths), a working party led by Professor Poswillo[14] was set up in 1989 to examine the need for general anaesthesia and sedation in dentistry outside hospital, and to develop guidelines for their safe use. In addition, part of their assessment was to comment on the provision for resuscitation, and undergraduate and postgraduate training in general anaesthesia, sedation and resuscitation. The working party concluded that: where general anaesthetics are given, full monitoring equipment in the form of an ECG, pulse oximeter, non-invasive arterial pressure and a capnograph together with a defibrillator should be available; there should be both a dental and an anaesthetic assistant present; there should be a fully equipped recovery facility with adequately trained staff; everyone who administers anaesthetics for dental surgery should be able to formally manage an airway, establish i.v. access, correctly give drugs used in resuscitation and be able to use a defibrillator; and that there should be an increase in postgraduate training in anaesthesia, sedation and resuscitation. The Clinical Standards Advisory Group's report on dental general anaesthesia in 1995[1] confirmed that the majority of dental practices had carried out the recommendations in the Poswillo Report, particularly with reference to basic monitoring. Unfortunately, the improved standards of care do not seem to have had any affect on mortality. Patients are continuing to die (still approximately two per year).

This leaves the basic question unanswered of why healthy people have unexplained cardiac arrests and die? One possible answer is the high propensity to arrhythmias in dental patients when halothane is used. The popularity of halothane for general anaesthesia in dental outpatients has continued because of the absence of a suitable alternative. However, with the advent of the new volatile anaesthetic agent, sevoflurane, the use of halothane needs to be re-assessed.

Sevoflurane is a halogenated ether which is non-irritant, has a pleasant odour and a low blood-gas solubility; such properties make it ideally suited to inhalation induction and maintenance of general anaesthesia for minor dental surgery in both adults and children. More importantly, Paris and colleagues[15] found that the incidence of arrhythmias with sevoflurane was 26% whereas with halothane it was 62%. Interestingly they found that only 6% of patients suffered arrhythmias during the recovery period; this may be relevant for outcome as Coplans and Curson in 1982[2] found that more than 50% of dental deaths occurred during the recovery period. The type of arrhythmias also differed[15]; with sevoflurane the associated arrhythmias were predominantly supraventricular whereas with halothane a far greater number of the more sinister ventricular arrhythmias were seen.

Deaths associated with general anaesthesia are always difficult to accept, particularly when they occur in children and young people with no pre-existing disease. Despite the time and money spent in recent years to improve the quality of care, patients undergoing general anaesthesia for dental procedures continue to have seemingly unprovoked cardiac arrests. Halothane, with its high incidence of ventricular arrhythmias, may no longer be the volatile agent of choice in these circumstances. Sevoflurane is now widely available and has been shown to produce rapid and smooth loss of consciousness during inhalation induction, is easy to use during maintenance of anaesthesia and has good recovery characteristics for day-care procedures. In addition, sevoflurane is associated with fewer cardiac arrhythmias. It may be that by using sevoflurane in place of halothane, further unexplained cardiac arrests in patients undergoing minor dental surgery can be prevented.

CLINICAL INVESTIGATIONS

Conscious awareness during general anaesthesia: patients' perceptions, emotions, cognition and reactions

D. Schwender, H. Kunze-Kronawitter, P. Dietrich, S. Klasing, H. Forst and C. Madler

Summary

We interviewed 45 patients, who answered advertisements ($n = 21$) or were referred by colleagues ($n = 24$), about their experience of intraoperative awareness using a standardized questionnaire. Auditory perceptions, hearing sounds or voices were mentioned by all patients (45 of 45): 33 of 45 patients understood and recalled conversations; 21 of 45 patients had visual perceptions; 12 of 21 recognized things or faces; 29 of 45 patients felt being touched; three patients had the sensation of moderate pain; and eight patients were in severe pain. Patients' feelings were mostly related to paralysis (27 of 45), helplessness (28 of 45), anxiety and fear (22 of 45); 18 were in severe panic. All patients (45 of 45) recognized the situation as a real event: 22 of 45 patients experienced unpleasant after effects; 11 suffered from anxiety and nightmares; and three developed post-traumatic stress disorder syndrome and required medical treatment. Twenty of 45 patients were especially attentive to emotionally relevant remarks on their own person, their disease and the course of their operation. The accuracy of sensory perception indicates a very high level of cognitive performance of patients during intraoperative awareness. (*Br. J. Anaesth.* 1998; **80**: 133–139)

Keywords: anaesthesia, general; anaesthesia, depth; memory; psychological responses

The incidence of awareness during general anaesthesia that can be recalled explicitly after operation has been reported to be 0.5–2%.[1–9] Patients waking up during their anaesthetic are awake, in agony, intensely fearful but completely helpless, thinking that something must have gone terribly wrong. After operation, they recall all of the details of the procedure and the shock of this experience may cause post-traumatic stress disorder (PTSD).[9–11] Characteristic symptoms of PTSD involve re-experiencing the event, sleep disturbances with recurrent nightmares, avoidance of stimuli associated with the event, numbing of general responsiveness or increased arousal, anxiety and preoccupation with death, that in some cases require long-term medical and psychological support or treatment.[9 12]

Information on what patients perceive and recall of events during general anaesthesia is based mostly on case reports.[13–21] Most of these case reports relate to the patient's actual experience rather than patient reactions or after effects of awareness. Consequences of intraoperative awareness have been described only on the basis of small series of patients.[22–29] Only two studies analysed patients' feelings during, and patients' reactions to, awareness. Evans studied 27 patients with recall after anaesthesia having selected his patients by advertising in four British newspapers.[30] Bias of this sample cannot be excluded because advertisements select a disproportionate number of patients with a strong interest in their own medical history (so-called complainers). Therefore, Moerman, Bonke and Oosting investigated 26 patients with experiences of awareness during anaesthesia referred by colleagues of the anaesthesia department of a large university hospital.[31]

In this study we have investigated two groups of patients with experiences of awareness. One group was collected from advertisements in four German newspapers and the Internet. Patients in the second group were referred by colleagues of the anaesthesia departments of one large university hospital and two large community hospitals. The incidence, quality, intensity and accuracy of sensory perceptions, emotions and feelings, cognition and realization, reactions, consequences and after effects during and after intraoperative awareness was assessed within and between groups.

Patients and methods

After obtaining approval from the local Ethics Committee, two groups of patients with experience of awareness during general anaesthesia were collected. In group 1, patients answered advertisements placed in four German newspapers and on the Internet. The text of the advertisement was as follows: "For scientific research and documentation on the subject of 'awake during general anaesthesia?' the Department of Anaesthesia of Munich University and the Science Department of the German state television, section SDR, are looking for patients who woke up

Table 1 Case reports, patient data, perceptions, feelings and sequelae

Patient No.	Time interval	Patients' data (sex, age, height, weight)	Operation	Perceptions during intraoperative awareness	Sequelae
Group 1					
1	13 yr	F, 31 yr, 160 cm, 80 kg	Dental surgery	Heard people talking: "Stop, she is waking up, she needs some more anaesthetic", saw silhouettes, no pain, no anxiety	None
2	12 yr	M, 26 yr, 194 cm, 85 kg	Operation of a funnel breast	Felt hands and arms during being positioned and heard voices say: "we won't get along this way, we have to lay him down"	None
3	20 yr	M, 63 yr, 169 cm, 84 kg	Total hip replacement	Heard voices and the sound of metal, saw silhouettes and felt that his leg was moved up and down, moderate pain, helpless, in panic, tried to alert someone	Exaggerated sensitivity to sounds for 1.5 yr
4	2 yr	F, 24 yr, 162 cm, 60 kg	Cholecystectomy	Heard voices, felt no pain, helpless and in panic, paralysed, tried to open eyes and to alert someone	None
5	21 yr	F, 63 yr, 163 cm, 55 kg	Nephrostomy	Heard voices and the sound of metal, unable to open eyes, no pain, no anxiety	None
6	4 yr	M, 47 yr, 176 cm, 140 kg	Arthroscopy knee	Heard a voice saying: "how can a man be so fat"	None
7	26 yr	F, 63 yr, 158 cm, 65 kg	Caesarean section	Felt skin incision and touch, unbearable pain, heard: "she moves, she is coughing", saw silhouettes, felt paralysed, helpless, in panic, tried to alert someone	Increased fear of future anaesthetics and operations
8	30 yr	F, 40 yr, 167 cm, 65 kg	Operation on external ear	Heard sounds and understood conversation, no pain, clear sight, tried to alert someone, felt paralysed	None
9	7 yr	F, 45 yr, 163 cm, 63 kg	Cardiac valve replacement	Heard the sound of metal and a voice saying: "the patient tries to move. He is waking up!" tried to move finger, felt paralysed, unable to open eyes, tried to talk, felt helpless, no fear, no pain	Nightmares, anxiety of being unable to open eyes, for instance, when driving a car
10	4 yr	F, 58 yr, 168 cm, 73 kg	Lower extremity fracture	Heard voices, felt skin incision and unbearable pain, saw silhouettes, unable to move, helpless, tried to alert someone	None
11	17 yr	F, 23 yr, 163 cm, 47 kg	Herniorrhaphy	Moved arm and heard voices saying: "she is awake, she needs more anaesthetic" no anxiety, no pain	Nightmares, could not stay in bed after waking up
12	2 yr	M, 55 yr, 198 cm, 90 kg	Parotid tumour	Heard voices talking about the patient's increase in blood pressure, no anxiety, no panic, no pain	None
13	2 yr	F, 46 yr, 161 cm, 95 kg	Operation of the cervical spinal column	Recalled conversation concerning her overweight: "how can a women be so fat ?" and other disgusting jokes about her body weight	Depression for several weeks
14	19 yr	M, 56 yr, 179 cm, 80 kg	Anal fissure	Heard voices and understood conversation about how he lay on the operation table	None
15	2 yr	F, 33 yr, 155 cm, 82 kg	Caesarean section (emergency)	Heard: "She is awake" saw silhouettes, unable to open eyes, felt unbearable pain, paralysed, helpless, in panic, tried to alert someone	Nightmares, increased fear of future anaesthetics and operations
16	5 yr	F, 55 yr, 159 cm, 59 kg	Multiple trauma (emergency)	Heard voices and conversation of medical staff, saw light, silhouettes, no pain	None
17	4 yr	F, 33 yr, 171 cm, 86 kg	Caesarean section (emergency)	Felt pain during skin incision, heard conversation: "What about the suction device?" Tried to move, felt paralysed, saw lights and silhouettes	Nightmares and sleep disturbances for 2 yr
18	20 yr	F, 44 yr, 164 cm, 77 kg	Abortion curettage	Heard sounds, saw light, no pain, felt paralysed, helpless, in panic	None
19	9 yr	M, 49 yr, 176 cm, 77 kg	Aortocoronary bypass (emergency)	Heard and recalled conversation during emergency defibrillation, felt the electrical shocks and heard a voice saying: "We won't get him", panic	Severe anxiety, post-traumatic stress disorder, psychotherapy
20	16 yr	F, 46 yr, 168 cm, 70 kg	Caesarean section (emergency)	Heard sounds and conversation, able to understand and recall conversation, no pain, heard the sound of the crying baby after delivery	None
21	5 yr	M, 55 yr, 174 cm, 75 kg	Aortocoronary bypass	Heard sounds, understood conversation, no pain, felt paralysed	Anxiety, depression unable to stay in his job as an electrician, post-traumatic stress disorder

Table 1 Case reports, patient data, perceptions, feelings and sequelae—*continued*

Patient No.	Time interval	Patients data (sex, age, height, weight)	Operation	Perceptions during intraoperative awareness	Sequelae
Group 2					
1	2 yr	F, 52 yr, 168 cm, 73 kg, (anaesthetist)	Abdominal hysterectomy, anaphylactic shock (emergency)	Heard the word: "You have to give epinephrine, realized the emergency situation, thinking this is no more routine management, guys you are in severe difficulties, but I am sure, that you are doing the right things, giving epinephrine", no anxiety, no pain	None
2	5 yr	F, 33 yr, 169 cm, 52 kg, (anaesthetist)	Excisional biopsy, breast tumour	High-dose fentanyl anaesthesia, awake during the whole surgical procedure, heard sounds and conversation, saw silhouettes and felt being touched during the operation, no pain, no anxiety	None
3	16 yr	F, 37 yr, 167 cm, 42 kg	Appendicectomy (emergency)	Heard sounds and voices: "Can we start with the operation now?" Tried to alert someone, felt paralysed, helpless, in panic, no pain,	Increased fear of future operations or anaesthetics
4	4 yr	M, 35 yr, 180 cm, 80 kg	Multiple trauma, laparatomy (emergency)	Heard voices, saw silhouettes, no pain, felt helpless and paralysed, in panic, thought: "Now I have to die", tried to alert someone	Fear to die
5	5 yr	F, 36 yr, 162 cm, 63 kg	Laparoscopic cholecystectomy	Painful feeling in the upper abdomen, tried to move, felt paralysed	None
6	1 yr	F, 34 yr, 170 cm, 70 kg	Thyroidectomy	Heard voices saying: "the tube is too big but, we do not have another", no pain	None
7	20 yr	M, 45 yr, 179 cm, 74 kg	Septorhinoplasty	Heard sounds, opened eyes, saw surgeon and light, felt pressure on his head, no pain	None
8	7 yr	F, 39 yr, 159 cm, 74 kg	Caesarean section (emergency)	Felt warm fluid flowing over her abdomen, tried to open eyes, fear of bleeding to death	Sleep disturbances, fear to die, post-traumatic stress disorder, psychotherapy
9	10 yr	M, 24 yr, 170 cm, 80 kg	Upper extremity fracture	Felt intratracheal tube, heard voices and conversation: "Now we can start with the operation", tried to open eyes, felt paralysed, no pain	None
10	6 month	M, 44 yr, 182 cm, 85 kg	Appendicectomy (emergency)	Heard voices, felt painful skin incision, paralysed, helpless, tried to alert someone	None
11	1 yr	F, 46 yr, 166 cm, 80 kg	Meniscectomy	Heard conversation: "We now take a photo and show it to her afterwards", felt hands touching her, helpless, paralysed, panic	None
12	10 yr	F, 60 yr, 174 cm, 93 kg	Laparatomy, peritonitis (emergency)	Heard surgeons saying: "Why do we always have to treat the complications of other medical centres? This woman is lost anyhow."	Anxiety, nightmares
13	1 yr	M, 43 yr, 180 cm, 86 kg	Dental surgery	Heard the surgeon saying something to the anaesthetist, saw the surgical gloves as a silhouette	None
14	21 yr	F, 30 yr, 172 cm, 58 kg	Tonsillectomy	Felt her mouth being opened, could understand conversation and recognised the surgeon, the medical staff and the operating theatre. Moderate pain	None
15	1 yr	M, 14 yr, 161 cm, 54 kg	Gastroscopy	Heard conversation, felt touch, felt suffocated and paralysed	None
16	8 yr	F, 34 yr, 175 cm, 68 kg	Caesarean section (emergency)	Felt being touched, tried to alert someone, felt paralysed, heard voices	None
17	6 yr	F, 34 yr, 165 cm, 79 kg	Appendicectomy	Heard the surgeon saying: "She needs some more anaesthetic, because she is a red haired nurse and everything is different and very special in her case."	None
18	8 yr	M, 50 yr, 181 cm, 80 kg	Aortocoronary bypass	Heard voices, saw lights and silhouettes	None
19	6 yr	F, 29 yr, 168 cm, 72 kg	Caesarean section (emergency)	Felt being touched, heard the sound of the crying baby	None
20	10 yr	F, 25 yr, 165 cm, 59 kg	Dental surgery	Opened eyes, saw the surgeon, who went to call for the anaesthetist, saying: "She needs some more anaesthetics "	None
21	11 yr	F, 38 yr, 172 cm, 80 kg	Appendicectomy (emergency)	Felt the tracheal tube and heard the surgeon saying: "The appendix is shortly before perforating."	None
22	2 month	F, 37 yr, 165 cm, 72 kg	Laparoscopic cholecystectomy	Felt the tracheal tube, felt helpless, anxious	None
23	4 month	F, 43 yr, 162 cm, 62 kg	Laparoscopy	Heard the voice of the anaesthetist, unable to open eyes	None
24	4 month	M, 64 yr, 172 cm, 68 kg	Cholecystectomy	Felt tracheal tube, heard voices	None

during surgery while the operation was going on. Your experience will be an important contribution to our work. Please contact us. Your replies will be regarded as confidential. Please reply to SDR, Science-Department 68028 Mannheim/Germany."

Patients in group 2 were referred by colleagues of the anaesthesia departments of a large university hospital (Institute for Anaesthesiology, Ludwig-Maximilians-University Munich, Klinikum Innenstadt) and two large community hospitals (Institute for Anaesthesiology, Klinikum Augsburg and Institute for Anaesthesiology, Klinikum Kaiserslautern) requesting that they refer all patients with experience of awareness regardless of when the experience had occurred or the anaesthesia had taken place.

All patients in the two groups were interviewed using our standardized questionnaire "Awareness during general anaesthesia". The questionnaire was subdivided into six sections: personal data, detailed description in own words, sensory perceptions, feelings and emotions, cognition and interpretations, reactions, consequences and after effects. The following data were collected.

(1) Personal data: patient's name and address, age, sex, height, body weight, date, place and type of surgery, and preoperative feelings of nervousness, anxiety and pain.
(2) In the second section, patients were allowed to give a detailed description in their own words of perceptions, feelings and thinking while being awake during the anaesthetic.
(3) Incidence, quality, intensity and accuracy of sensory perceptions within the different sense modalities. *Auditory modality*: loud, low, close, far away, identification of the direction of the sound source, recognition of sounds or voices, understanding of language and conversation. *Visual modality*: able to describe light, shades, silhouettes, clearly or everything looking hazy, able to recognize things or people, either isolated or within a visual context. *Tactile modality*: feeling of being touched, quality and localization of sensation. *Paralysis*: unable to move arms, legs, head, vocal cords or other sites. *Nociceptive modality*: feeling pain, intensity, ranging from none, moderate to severe (0, 1, 2), identification of painful body part.
(4) Feelings and emotions differentiated into helplessness, weakness, fear and panic, with intensity ranging from none, moderate to severe (0, 1, 2).
(5) Interpretation of the situation and cognition, interpretation as dream or reality, estimation of duration and whether patient is trying to alert anyone or make signs.
(6) Patients' reactions, consequences for daily life and after effects: anxiety, fears, nightmares with intensity ranging from none, moderate to severe (0, 1, 2). Other consequences for daily life such as re-experiencing the event, numbing of general responsiveness, increased arousal, loneliness and lack of confidence in future life. Changing of opinion on anaesthesia and surgery and fear of repetition or more fear of future anaesthetics or surgeries. Duration of symptoms and whether the symptoms required medical treatment or a PTSD syndrome developed.

The last question was whether the patient informed the anaesthetist, surgeon, ward staff, general practitioner, partner, family or friends and what was their reaction.

STATISTICAL ANALYSES

Data are presented as mean (SD). For differences between groups, groups were compared using the Mann–Whitney *U* or chi-square test. Subgroups of patients were compared using chi-square or Fisher's exact test (two-sided). Differences were considered significant if $P < 0.05$, after Bonferroni's correction for multiple comparisons.

Results

During an 8-month period, 45 patients were analysed; 21 patients replied to the advertisements (group 1) and 24 patients were referred from the three hospitals involved in the study (group 2). In total, 45 questionnaires of awareness during general anaesthesia were analysed.

In table 1, case reports, patient data, a short description of patients' perceptions and feelings, and postoperative sequelae are presented. The two groups were comparable in patient data, type of surgery, a wide range of incidence, quality, intensity and accuracy of perceptions, emotions, cognition, reactions and after effects. Details on patients (sex, age, weight, height, time interval between interview and anaesthesia), type of surgery, patients' descriptions of their experiences of awareness in keywords and postoperative sequelae are presented in table 1. Mean age of the patients was 41.7 (range 14–64) yr, mean body weight was 73.9 (47–140) kg and body height 169.75 (153–194) cm. Thirty patients were female and 15 male, and the time interval between the event and the interview was 9.6 yr (range 0.1–30 yr). Events occurred during anaesthesia for elective general abdominal (n=16), cardiothoracic (n=5), orthopaedic (n=6), gynaecological (n=4) or ear–nose–throat or dental surgery (n=7). Seven cases of awareness were observed during Caesarean section and 14 patients underwent emergency surgical procedures.

In table 2 the incidence, quality, intensity and accuracy of perceptions, emotions, cognition, reactions and after effects are presented for group 1, group 2 and for both groups combined.

SENSORY PERCEPTIONS WITHIN THE DIFFERENT SENSE MODALITIES

All patients (45 of 45) had auditory perceptions, hearing sounds or voices. The sound source was described as loud in 28 of 45 and close in 29 of 45 patients; 33 of 45 patients understood and recalled conversations. Patients in group 1 heard the sounds louder and closer when being aware and were significantly more often able to understand conversations; 21 of 45 had visual perceptions, and 10 of these 21 described their vision as clear, while 10 patients saw only silhouettes. Twelve patients recognized things or faces and 10 were able to localize this in the visual context of the operating room. Twenty-nine patients felt being touched, 28 of these were able to localize exactly where they felt the touch. Thirty-four patients felt no pain, three patients felt moderate and eight patients severe pain. All patients with pain perceptions were able to localize exactly were they felt the pain. Twenty-seven patients had the feeling of paralysis, 22 of whom were able to localize the paralysed body parts.

EMOTIONS

Twenty-eight of 45 patients felt helpless, 22 of 45 had feelings of anxiety and fear, four had moderate fear and 18 were in severe panic.

COGNITION

All patients (45 of 45) recognized their situation as a real event. The estimated duration of the awareness episode during anaesthesia ranged from 1 to 60 min (mean duration 7.73 min). Thirty-one of 45 patients tried to alert someone or to make signs.

REACTIONS AND AFTER EFFECTS

Twenty-two of 45 patients suffered from after effects of their awareness episode; 21 changed their opinion on future anaesthetics and operations, 11 suffered from anxiety during the day and 11 suffered from nightmares. In nine patients the awareness episode had consequences for their daily life, three required medical treatment and three patients developed PTSD syndrome. The mean duration of after effects was 0.84 (range 0.1–5.0) yr. Patients in group 1 had nightmares more often and after effects lasted significantly longer compared with those in group 2. Forty of 45 patients informed the anaesthetist, surgeon, medical staff, family or friends after operation. The response appeared to be affirmative, ranging from sympathy and explanation (19 of 40), or defensive, ranging from disbelieve to denial (10 of 40).

We subdivided all patients into two groups and compared those patients with and without after effects. Almost all patients with after effects had changed their opinion on anaesthesia and surgery ($P = 0.001$). Patients with after effects were significantly more often helpless ($P = 0.001$) and in fear or severe panic ($P = 0.049$) when being aware during operation compared with patients without after effects. There was no difference between patients with and without after effects regarding incidence and intensity of pain perception ($P = 0.856$) and other sensory perceptions, emotions and cognition.

Discussion

The two patient groups (21 patients who answered the advertisement (group 1) and 24 patients referred by colleagues of the large hospitals (group 2)) were comparable in patient data, type of surgery, a wide range of perceptions, emotions and cognition during their awareness episode, and incidence of after effects. Differences were found only in the quality of auditory perception and the incidence of understanding of language. Patients in group 1 heard the sounds louder and closer and were significantly more

often able to understand conversations. One important difference between groups was that group 1 patients had nightmares more often and after effects lasted significantly longer than in group 2 (mean duration 1.59 *vs* 0.08 yr). This may be because of a bias in patient collection, indicating that patients who answered the advertisements had severer and longer lasting postoperative sequelae and possibly a stronger interest in their own medical history (so-called complainers). Our data support the suggestion of Moerman, Bonke and Oosting that it cannot be excluded completely that by advertising, a patient sample is biased and a disproportionate number of "complainers" may be selected with a strong personal interest in their own medical history.[31]

As in the studies of Moerman, Bonke and Oosting[31] and Evans,[30] reports of awareness during anaesthesia in our analyses occurred not only during "high risk awareness" surgical procedures such as obstetric, cardiac or emergency surgery. The majority of awareness cases in our study occurred during elective ear, nose, throat, dental, general, abdominal, orthopaedic or gynaecological surgery, indicating that awareness during anaesthesia is not only a problem of special surgical procedures but may occur occasionally during anaesthesia for almost any elective procedure.

The incidence of perceptions within the different modalities during intraoperative awareness correspond well with data reported in the literature.[1,9,15,24,26,27,30,32] All patients were able to hear, indicating that the auditory modality is the most important sensory channel during intraoperative awareness. A high percentage of patients, especially those who heard loud sounds with the sound source close by, were able to understand language and remember conversations after operation. Twenty patients were especially attentive to emotionally relevant remarks, that is they recalled remarks on their own person, disease and course of the operation (two cases of derogatory remarks, two cases of very meaningful remarks and 15 cases of some type of meaningful remarks). This finding may support a widespread belief that meaningful words and remarks are recalled more easily than neutral sounds and have a greater impact on the patient.[25,28,29,33–36] On the other hand, 25 patients recalled only general theatre chat and noise.

Visual perception was reported by nearly 50% of our patients. This experience has been rarely documented and exceeds incidences reported by Moerman, Bonke and Oosting (27%) and Evans (33%). Furthermore, 50% of our patients with intraoperative visual perceptions had clear sight and could recognize things and faces within a clear visual context of their visual field. A high percentage of patients had tactile sensations and almost all were able to localize the body parts exactly where they were being touched. The high incidence of paralysis in our study corresponds well with data from the literature and in almost all cases the paralysed body parts could be identified.

The incidence of pain perception in our study (25%) was less than that reported in the literature (40%).[30,31] Nevertheless, 17.8% of patients had severe pain. All patients were able to localize the body part exactly where the painful stimuli occurred. Jones estimated the incidence of conscious awareness with pain to be lower than 1 in 3000 anaesthetics, and the incidence of conscious awareness without pain perception to be 1–3 in 300 anaesthetics.[9] This would imply that painful feelings occur in less than 10% of patients who are aware during anaesthesia. Our data and those of Moerman, Bonke and Oosting, and Evans exceed this estimate; this may be a result of the small sample size and the possible disproportionate number of "complainers" in our study.

Two-thirds of patients had emotional distress during their intraoperative awareness and felt helpless or anxious; 40% felt severe distress and panic, an incidence significantly lower than that reported by Moerman, Bonke and Oosting (92 %)[31] and Evans (78%).[30]

The percentage of patients who suffered after effects (50%) was slightly lower than in the study of Moerman, Bonke and Oosting.[31] Their symptoms corresponded with those reported in the literature.[9–12,22,28,37–40] Anxiety during the day, nightmares and sleep disturbances with consequences for daily life were most frequently mentioned. Most often, patients with after effects changed their opinion on anaesthesia and surgery with more fear for future procedures and that such an episode could happen again. Three patients required medical treatment after operation because of the development of PTSD. Why some patients experience after effects or develop PTSD and others do not cannot be explained from the present data. In contrast with Moerman, Bonke and Oosting,[31] we did not find a trend towards a correlation between intraoperative pain perception and the incidence of after effects in our patients. Nevertheless, our patients with after effects felt significantly more helpless, fearful or severe panic during operation than patients without after effects.

The percentage of patients who informed an anaesthetist, surgeon, hospital staff, family or friends (89%) was higher in our study than reported previously.[30,31] This may reflect the increasing popularity that the topic of awareness during anaesthesia has gained in the lay press within the past years and the growing general knowledge of such problems. In contrast with Moerman, Bonke and Oosting, and Evans, responses were mostly affirmative, ranging from sympathy to explanation of the event, although responses of disbelief and denial occurred in some cases. These observations may indicate a steadily increasing understanding of the phenomenon and problems of intraoperative awareness on the part of the patient in addition to anaesthetists and surgeons.

In summary, our data indicated a high accuracy of sensory perceptions, especially auditory perceptions, understanding and recall of conversations, and a high level of cognitive performance of patients during intraoperative awareness. The results illustrate the need for the anaesthetic and operating theatre staff to realize that awareness may be occurring during general anaesthesia.

Preoperative assessment for difficult intubation in general and ENT surgery: predictive value of a clinical multivariate risk index†

J. Arné, P. Descoins, J. Fusciardi, P. Ingrand, B. Ferrier, D. Boudigues and J. Ariès

Summary

Several clinical multifactorial indexes have been described for predicting difficult laryngoscopy or intubation, or both, mostly in general surgery, and less frequently in ENT surgery. The objective of this study was to develop and validate a single clinical index for prediction of difficulty in tracheal intubation in both ENT and general surgery. We studied a population of 1200 consecutive ENT and general surgical patients. Clinical criteria were tested using univariate and multivariate analysis. Difficult intubation was defined as requiring unusual techniques. Logistic regression identified seven criteria as independent predictors of difficult tracheal intubation: previous history of difficult intubation; pathologies associated with difficult intubation; clinical symptoms of pathological airway; inter-incisor gap and mandible luxation; thyromental distance; head and neck movement; and Mallampati's modified test. Point values were assigned to each of these factors in proportion to regression coefficients representing the relative weight of each predictive intubation difficulty factor, the sum comprising the score. The best predictive threshold was chosen using a receiver operating characteristic curve. We then prospectively studied and validated the score in a population of 1090 consecutive ENT and general surgery patients. The sensitivity and specificity of the predictions were 94% and 96% in general surgery, 90% and 93% in non-cancer ENT surgery, and 92% and 66% in ENT cancer surgery, respectively. (*Br. J. Anaesth.* 1998; **80**: 140–146)

Keywords: Intubation tracheal, difficult; surgery, general; surgery, otolaryngological

Difficult tracheal intubation may increase anaesthetic morbidity and mortality, especially during obstetric[1 2] and other types of anaesthesia.[3 4] Several prospective studies have identified various individual clinical symptoms possessing a significant association with laryngoscopy or intubation difficulties.[5–13] Sensitivity and positive predictive values of these individual signs are low, ranging from 33% to 71% for sensitivity. Thus six studies have challenged multifactorial prediction indexes of difficult tracheal intubation or difficult view of the glottis, or both; five found a decrease in falsely predicted laryngoscopy or intubation difficulty,[14–18] whereas no improvement in sensitivity was found by Tse, Rimm and Hussain.[19] Another study[20] calculated the probability of difficult laryngoscopy using different combinations of predictive signs and a multivariate analysis; however, the optimal predicting level of these associations was not determined. Finally, comparison of these studies led to the conclusion that a multifactorial clinical index generally improves the prediction of difficult laryngoscopy or tracheal intubation.

Studies of multifactorial clinical index assessed predictions of difficult laryngoscopy in ENT and oral,[14] general[15 17–19] and gynaecological and obstetric populations.[16 20] To date, no single multifactorial index can be applied to the various surgical populations. Moreover, most, with the exception of Wilson's index, have not been validated prospectively.[17 21] However, Wilson's index is validated only for prediction of difficult laryngoscopy, as defined by Cormack and Lehane,[22] as inability to see the glottis in the standard intubation position. Finally, no index, including Wilson's, has been validated prospectively for detection of difficult tracheal intubation per se.

For these reasons, we undertook the development and validation of a predictive clinical multifactorial risk index, based on a multivariate analysis, aimed at predicting difficult tracheal intubation, both in general and ENT surgery.

Patients and methods

This prospective study was conducted in two steps. First, 12 different criteria, selected because of previously demonstrated statistical associations with difficult laryngoscopy or tracheal intubation, were recorded in a consecutive series of patients. Using a multivariate analysis, we then established a multifactorial clinical index to predict difficult tracheal intubation. In a second prospective step, this index was tested, and its performances evaluated in another series of patients.

INITIAL STUDY

During an 18-month period, any patient older than 15 yr of age undergoing ENT or general surgery

---

with tracheal intubation was considered as potentially eligible for this prospective study. Five senior anaesthetists served as investigators and 1200 consecutive patients were included during this period based on the following factors recorded during preoperative consultation.

(1) Weight, height and age.

(2) Knowledge by the patient of previous difficulty with laryngoscopy or intubation, that is had the patient been informed previously of a difficulty during a previous operation in another medical centre.

(3) Pathologies associated with difficulties in laryngoscopy or intubation, such as malformation of the face,[23] acromegaly,[24] cervical spondylosis with limitation of neck movements,[6] occipito–atlanto–axial disease,[7] tumours of the airway and long-term diabetes mellitus with "stiff joint syndrome".[25–27]

(3) Clinical symptoms of airway pathology, such as dyspnoea related to compression of the airway, dysphonia, dysphagia and sleep apnoea syndrome[28 29] (this syndrome was considered either in the case of a previously fully documented illness or in the case of snoring associated with two other major symptoms among sudden arousal with choking, excessive day time sleepiness or unrefreshing sleep).

(4) Inter-incisor gap (IG) and mandible luxation (ML) evaluated using three levels: (i) IG <3.5 cm and negative ML; (ii) IG 3.5–5 cm and no ML; (iii) IG >5 cm or positive ML.

(5) Tooth morphology: buck teeth or normal teeth.

(6) Cervical morphology: short thick neck or normal neck.

(7) Thyromental distance measured with the head fully extended: < or >6.5 cm.

(8) Maximum range of the head and neck movement, measured as described by Wilson and colleagues[17]: the patient was asked to fully extend the head and neck while a pencil was placed vertically on the forehead. The orientation of the pencil was adjusted so that it was parallel to a distant window frame. Then, while the pencil was held firmly in position, the head and neck were fully flexed and the pencil was sighted against the horizontal of the window frame to judge if it had moved through 90°. This criterion was graded into three levels: < 80°; near 90° (90°±10°); > 100°.

(9) Mallampati's modified test[11] divided into four classes: class I = soft palate, fauces, uvula and pillars seen; class II = soft palate, fauces and uvula seen; class III = soft palate and base of uvula seen; and class IV = soft palate not visible.

The results of these factors were noted.

In the operating room, each patient was placed on the table with the head and neck in the optimal intubating position (sniffing position). The anaesthetist chose an anaesthetic induction technique according to the preoperative assessment, his own beliefs and any concomitant medical problems. General anaesthesia with neuromuscular block (vecuronium 0.1 mg kg^{-1}) was chosen by anaesthetists when they thought that intubation would be easy or when this mode of induction was thought to be the most appropriate for any other specific medical problem. When any difficulties were anticipated, a topical anaesthetic was used with gradual application of 5% lidocaine 120 mg from the lips to the glottis with 1% lidocaine 30 mg on the trachea using a spray (Abbott Laboratories, North Chicago IL, USA), accompanied by slight anaesthesia (midazolam 1 mg, fentanyl 50 µg and propofol 1 mg kg^{-1}) maintaining spontaneous breathing. Then, laryngoscopy was performed using a Macintosh blade and the glottic view was noted using Cormack and Lehane's classification[22]; intubation was then attempted. Adjuvant manoeuvres, such as external cricoid pressure or upward pressure on the epiglottis with the tip of the blade, or both, were also used. When the first attempt failed, a second was made using the large Miller blade and other manoeuvres. In case of failure, a second senior anaesthetist was required for further attempts using the same techniques and deepening anaesthesia if warranted. In case of failure by the second anaesthetist, intubation was said to be difficult and other special devices, not available routinely in every operation room, were considered. Thus intubation was defined as difficult when special techniques were required, as assessed by two senior anaesthetists. If their evaluation differed, intubation was not considered as difficult. The special techniques used in our department are: gum elastic bougies, fibreoptic intubation, the Piquet–Crinquette–Vilette's laryngoscope,[30] which is used mainly in France for ENT patients, and the Bullard laryngoscope.[31–33] Several other laryngoscopes are also available but were not used.

STATISTICAL ANALYSIS

The association between different variables and difficulty in intubation was evaluated using the chi-square test for qualitative data and the Student's t test for quantitative data. $P < 0.05$ was regarded as significant. Sensitivity, specificity, positive and negative predictive values were calculated according to standard formulae. Stepwise logistic regression analysis, using the SAS program, was performed with data from 1200 patients to identify multivariate independent predictors of difficult intubation. Variables in the predictor sets were found by a forward selection process such that introduction of additional variables was permitted only if P remained less than 0.05. Regression coefficients of each predicting factor in the final regression analysis were then used as "points", their sum giving "the exact score". These coefficients represent the relative weight of each predictive factor assessing difficult intubation. The discriminant function coefficient assigned to each statistically significant factor was then multiplied by a fixed value and rounded to the nearest whole number to derive a "point" value suitable for clinical purposes. Addition of these "point" values led to a simplified score.

SCORE VALIDATION STUDY

The effectiveness of this simplified score was tested subsequently by 17 senior anaesthetists in 1090 consecutive patients. The aim of this second series was to validate prospectively the simplified index and its optimal predictive level when used by several investigators. In this study, we calculated index performance in the prediction of difficult tracheal intubation. The same design was used as in previous studies.

Table 1 Number of patients undergoing different surgical procedures in the two studies (initial and validation studies)

Surgical population	Initial study (*n*)	Validation study (*n*)
ENT surgery		
Cancer	187	83
Non-cancer	425	290
General surgery		
Oral	312	421
Neurosurgery	102	
Abdominal	92	53
Gynaecology	29	53
Orthopaedic	28	32
Urology	25	88
Cardiac		70
Total	1200	1090

Results

INITIAL STUDY

As shown in table 1, among the 1200 patients included, 588 were undergoing general surgery; neurosurgical procedures were mainly lumbar slipped disc or intracranial lesions; orthopaedic operations were mainly joint prosthesis, without any atlanto–axoido–occipital joint surgery. A total of 425 patients were undergoing non-cancer ENT surgery, including 12 (2.8%) patients for sleep apnoea syndrome; 187 patients were undergoing ENT cancer surgery, including laryngectomy, pharyngectomy, glossectomy and endoscopy for diagnosis. For the whole population, in 50 patients (4.2%) the trachea was difficult to intubate: 12 (2.0%) undergoing general surgery, 15 (3.5%) ENT non-cancer surgery and 23 (12.3%) ENT cancer surgery. No intubation failed completely.

In tables 2 and 3, the number of difficult tracheal intubations is given according to Cormack and Lehane grades and mode of induction selected, respectively. There were no significant differences in weight or height between patients without difficult intubation (mean 67 (SD 13) kg and 168 (9) cm) and patients with difficult intubation (67 (12) kg and 169 (7) cm). Patients with a trachea difficult to intubate were older (50 (17–78) yr) than those with easier ones (43 (15–92) yr) ($P = 0.006$). Each of our qualitative criteria (airway pathology, clinical symptoms, etc.) showed a significant association with difficult intubation, after univariate analysis, except for tooth morphology. Univariate analysis identified nine factors, including age, with a significant association with difficult intubation (table 4).

Stepwise logistic regression analysis identified seven factors as independent predictors of difficult

tracheal intubation among the 12 factors studied (table 5). The multivariate discriminant function coefficient of these factors, which represents the relative predictive value of each variable, was used as "points", their sum giving the exact score. For clinical purposes, we simplified this score by arbitrarily multiplying each of the points by 3.15 and then rounding to the nearest whole number to derive a simplified point value for the factor and a simplified score. The risk factors and corresponding "points" of these two scores are presented in table 6. The optimal predictive level of the scores were determined using receiver operating characteristic curve (ROC) analysis (fig. 1). This method consists of constructing a graphic representation of each possible score level where the *Y* coordinates are the sensitivities and the *X* coordinates are the false positive percentages (= 1 − specificity). The optimal predictive level is that which is nearest to the ideal point (sensitivity = 100%, false positive = 0%). Our ideal point was 3.55 for the exact score and 11 for the simplified score (fig. 1). ROC analysis of the two scores provided a high and comparable discriminant power for predicting difficult tracheal intubation as the area under the curve was 0.958 for the exact score and 0.956 for the simplified score. Therefore, simplification of the exact score into the simplified score did not significantly decrease performance. Statistical performances of the simplified score for predicting difficult tracheal intubation in the different surgical groups, with the optimal level of 11, are presented in table 7.

SIMPLIFIED SCORE VALIDATION STUDY

Among the 1090 patients included in the validation study, 717 were undergoing general surgery, 290 for non-cancer ENT surgery and 83 for ENT cancer surgery (table 1). In the overall population, 41 patients (3.8%) had a trachea which was difficult to intubate: 18 (2.5%) undergoing general surgery, 10 (3.4%) ENT non-cancer surgery and 13 (15.7%) ENT cancer surgery. No intubation failed. Statistical performances of the score for predicting difficult tracheal intubation in the different surgical groups are presented on table 7.

Discussion

Ideally, any preoperative assessment of difficult tracheal intubation should have high sensitivity and specificity and result in minimal false positive and false negative values. The advantage of our clinical multivariate risk index is the association of high specificity with improved sensitivity in comparison with previous multivariate studies. False negative prediction is therefore minimized. In addition, the same risk index can be used for both general and ENT surgical populations.

The consequences of a false negative result may be deleterious and even life-threatening. Our predictive risk index results in minimal detection failure of difficult tracheal intubation whatever the studied population. We believe this is our most important finding. Our results are comparable with those described previously by El-Ganzouri and colleagues[18] regarding preoperative assessment of the difficult airway. Indeed, multivariable composite risk index performs better than single independent criteria. Previous work based on multivariate analyses, mainly emphasized the reduction in false positive prediction compared with a single criterion.[14–18] Although this may result in less time expended or in fewer unnecessary manoeuvres, our belief is that decreasing false negative prediction is the main goal of any prediction.

Comparing predictive values obtained from different studies based on multivariate analyses requires a brief review of the limitations of predictive risk indices and diagnostic tests. This point has been summarized previously by Dupuis, Nathan and Wynands[34]

Table 6 Risk factors retained by the multivariate analysis for predicting difficult tracheal intubation, and the corresponding points of the exact and simplified score "Points" of the exact score are given by the values of multivariate discriminant function coefficient of every factor. The "points" of the simplified score were obtained by multiplying the "points" of the exact score by 3.15 and then rounding the results to the nearest whole number

Risk factor	"Points" of the exact score	"Points" of the simplified score

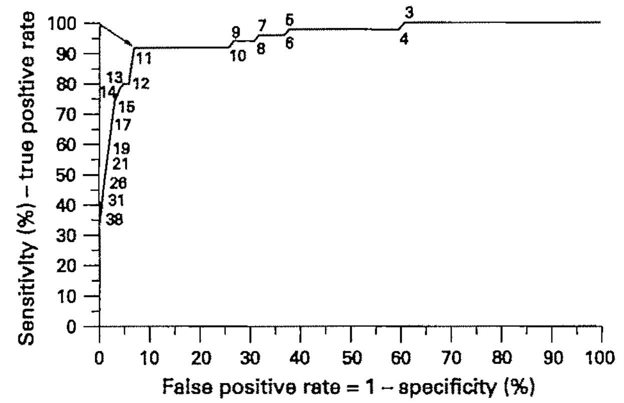

Figure 1 Receiver operating characteristic curve for the simplified score to predict difficult tracheal intubation in the global population. The numbers on the curve represent the different levels of the risk index. The sensitivity of the risk index is highest at low score values, whereas specificity is low. Highest score values give very good specificity at the expense of a reduced sensitivity. The cut-off value of 11 gives the best compromise between sensitivity and specificity.

for cardiac risk indices. A low prevalence of the "disease" (herein difficult intubation) in the test population causes the positive predictive value to decrease and the negative predictive value to increase. In our series, the overall incidence of difficult intubation was increased (3.8%) compared with previous studies[16–18] (see table 8). It might thus have favoured low negative predictive value and high positive predictive value. Nevertheless, our risk index allows the highest negative predictive value, as shown in table 8. This indicates that the risk index adequately eliminates patients without difficulties in tracheal intubation at a score level of 11, and suggests that it may be applicable to other institutions, even with a high incidence of difficult intubation. However, our risk index performs poorly for positive predictive values (30–52%). This implies that difficult intubation is falsely predicted in approximately two of three patients, or one of two patients. This is a common limitation of any risk index, as values of 9–21% have been described previously.[16–18] In our studies, as in others (table 8), the incidence of difficult intubation seems to be a major determinant of positive prediction. Nevertheless, we believe that decreasing false negative prediction is far more important than diagnosing difficult intubation in unaffected patients.

Another characteristic of the ideal predictive method is both high sensitivity and specificity. A general problem encountered with predictive risk indexes is the fact that high derived index values result in high positive predictive values, obtained with reduced sensitivity and an increased incidence of false negative predictions when considering minimal index score values. In constrast, low index score values are associated with high sensitivity and reduced false negatives, but specificity is low and false positives are increased.[34] This relationship between sensitivity and specificity is demonstrated by the ROC representation. When considering our simplified risk index at the level of 11, both sensitivity (90–94% in the various surgical populations) and specificity (66–96%) are high, especially in general surgery and ENT non-cancer surgery (see table 7). These results show improvement compared with previous studies. Sensitivity and specificity were 75%

Table 7 Predictive values of the simplified score when it is equal to or higher than 11 (best predicting cut-off) in the different surgical groups: initial and validation study (95% confidence intervals in parentheses). DI = difficult tracheal intubation

	Global population		General surgery		ENT non-cancer surgery		ENT cancer surgery	
	Initial study	Validation study	Initial study	Validation study	Initial study	Validation study	Initial study	Validation study

Misclassification rate (%)	7	7	2	4	5	8	26	30

Table 8 Assessment of difficult intubation in predictive clinical multivariate studies. *Only 10% of the population had a pregnancy of more than 6 months. The different predictive values and incidences of false negatives were estimated after calculations based on the data given by the different studies

Score	Definition of difficult intubation	Population studied	*n*	Incidence (%)	Sensitivity (%)	Specificity (%)	Positive predictive value (%)	Negative predictive value (%)	False negative	Misclassification rate (%)
Wilson and colleagues[17]	Cormack 3 and 4	General surgery?	778	1.5	75	88	9	99	0.4%	12
Pottecher and colleagues[16]	Cormack 3 and 4	Gynaecological and obstetric*	663	5.8	70	84	21	98	1.8%	17
El-Ganzouri and colleages[18]	Cormack class 4	General surgery?	10507	1	65	94	10	99	0.3%	7
Our simplified score	Unusual techniques	General surgery	717	2.5	94	96	37	99	0.2%	4
Our simplified score	Unusual techniques	Global population	1090	3.8	93	93	34	99	0.3%	7

and 88% for Wilson and colleagues,[17] 70% and 84% for Pottecher and colleagues[16] and 65% and 94% for El-Ganzouri and colleagues.[18] In addition, with the exception of El-Ganzouri and colleagues, these studies did not take into account the inverse relationship between sensitivity and specificity. Conversely, in the first part of our study we found that the value of 11 produced the best compromise between sensitivity and specificity, that is this is the point where the test assigned the fewest patients to the wrong category. The second part of the study confirmed the cut-off value of 11 and the misclassification rate of 7%, regardless of the number of investigators. This indicates that the reliability of the simplified risk index is investigator-independent. Finally, the main advantage of the risk index is a high sensitivity without a reduction in specificity when applied to a general surgical population. When applied to cancer ENT surgery, both sensitivity and specificity are comparable with values obtained in previous studies. The risk index can therefore be used for prediction in both general and ENT surgery.

The choice of anaesthetic technique (spontaneous or IPPV) was dependent on the anaesthetist and this may have introduced a potential bias into the study. In fact, the two modes may have potentially led to overestimation of the difficulties in tracheal intubation. During spontaneous ventilation, the patient may constrict airway muscles, reducing the laryngoscopic view, thus overestimating intubation difficulty. We tried to minimize this problem by using a meticulous and effective topical anaesthetic. In addition, when a second anaesthetist was called to intubate, he had the opportunity to deepen anaesthesia if warranted. In fact, it is not clear that the general anaesthesia mode allows a better glottic view, because with neuromuscular block the larynx is moved forwards and downwards,[35] decreasing the alignment between the pharyngeal and laryngeal axis, and thus the laryngoscopic view. In our first study, the mode of induction chosen seemed inappropriate in 298 patients (24.8%) (table 3). In 290 of 332 (87%) patients, the choice of sedation with topical anaesthesia was inappropriate, suggesting overestimation of difficult intubation. This shows that the choice of sedation and topical anaesthesia did not preclude misdiagnosis of difficult intubation in almost 87% of patients. Finally, we believe that in studying prediction of difficult intubation in different surgical populations, different modes of induction need to be included, even if a single standard method is ideal. Of previous studies, only that of Rocke and colleagues[20] used a single standard technique (thiopental followed by succinylcholine) when a difficult intubation was anticipated, as the population was limited to Caesarean section.

Another methodological question is still at issue: how to define a difficult intubation and why did we not use the Cormack and Lehane classification?[22] The reason was mainly because this classification relates only to the view gained at laryngoscopy. Despite grades 3 and 4 representing the most frequent difficulties in tracheal intubation, other causes may be involved, especially during cervical, thoracic or ENT surgery. In our first series, difficulty in glottic view was the main cause of difficulty in tracheal intubation (table 2). However, in two ENT patients, insertion of the tracheal tube was impeded by limited mouth opening, despite a good glottic view. We found the same problem in three other patients: one undergoing general surgery and two ENT surgery. In addition, numerous patients with Cormack and Lehane grade 3 and some grade 4 underwent successful intubation with usual blades and simple manoeuvres, such as external cricoid pressure or upward pressure on the epiglottis with the tip of the blade. These situations were not classified as difficult (table 2) according to our definition. With our definition for difficult intubation, our risk index aimed at predicting in which patients special laryngoscopes or techniques, not usually present in each operating room, may be required.

Our clinical predictive index has some limitations. We studied only a small number of patients with cervical spine pathology, and neither spondylosis or rheumatoid arthritis were included. Patients with occipito–atlanto–axial disease are also a high risk group,[7] not present in our studies. Thus it is possible that additional radiological evaluation may usefully complete the clinical prediction in this particular group. Another limitation is the item "previous knowledge of difficult intubation". To elucidate this during consultation is dependent on previous surgery, previous general anaesthesia with or without tracheal intubation and awareness of the patient about previously encountered difficult intubation. Omission of this information in the nine patients with this item in the initial series (table 4) would have failed to predict difficult intubation in two of seven patients with confirmed difficult intubation.

With these limitations in mind, the clinical predictive index can be applied to both general surgical and ENT populations with a general accuracy (misclassification rate 7% and errors in negative predictive value 1–2%). Its clinical use is easy, as one uses only seven risk factors and the "points" listed in table 6. Difficult intubation can be predicted if the score exceeds 11. When a score less than 11 is found, a difficult intubation can be excluded, with a risk of false prediction of 1–2%.

Pre-emptive effect of multimodal analgesia in thoracic surgery

E. DOYLE AND G. M. R. BOWLER

Summary

Thirty subjects undergoing posterolateral thoracotomy were allocated randomly to receive one of two analgesic regimens: group Pre received i.v. morphine, i.m. diclofenac and intercostal nerve blocks from T2 to T11, 20 min before operation and placebo injections after operation. Group Post received placebo injections before operation, and i.v. morphine, i.m. diclofenac and intercostal nerve blocks from T2 to T11 at the end of surgery, before discontinuation of anaesthesia. Visual analogue pain scores, extent and duration of intercostal nerve block, analgesic consumption and complications were assessed during the postoperative period by a single blinded observer. Subjects were followed-up for a minimum of 12 months to determine the incidence of post-thoracotomy pain syndrome. During the first 48 h after operation there were lower pain scores in group Pre when taking a vital capacity breath but there were no significant differences between the groups in any other measure. The effects of pre-emptive analgesia given before surgery appeared to be relatively modest in terms of analgesia, analgesic consumption and long-term outcome and were of limited clinical significance. (*Br. J. Anaesth.* 1998; **80**: 147–151)

Keywords: analgesia, pre-emptive; surgery, thoracic; complications, post-thoracotomy syndrome

Evidence from basic research in mechanisms of pain suggests that administration of analgesic drugs may be more effective if given before, rather than after, a nociceptive stimulus.[1–3] Some clinical work supports this concept when using local anaesthetic techniques,[4 5] systemic opioids,[6–8] extradural opioids,[9] ketamine[7] and combined or balanced analgesic regimens.[10] Other studies have found little difference in the degree of postoperative pain or requirements for analgesics between groups where analgesics are administered after rather than before the start of surgery using opioids,[11 12] local anaesthetics,[13–17] non-steroidal anti-inflammatory drugs (NSAID)[18 19] or combined techniques.[20–22]

The proposed mechanism of this pre-emptive effect is that administration of analgesia before a nociceptive stimulus reduces the degree of sensitization produced in the nervous system by the stimulus and facilitates subsequent treatment. Noxious stimulation generates reflex hyperexcitability in the dorsal horn of the spinal cord.[23] This central sensitization prolongs and increases sensitivity to noxious stimuli over an expanded receptive field (hyperalgesia), results in pain from normally innocuous stimuli (allodynia) and in spontaneous pain. Repetitive noxious stimuli evoke a progressively escalating response in the spinal cord which further magnifies the pain.[24] An extension of this concept is that effective analgesia administered before a nociceptive stimulus may also reduce the risk of a postoperative chronic pain syndrome.[25]

It is important to discriminate between the effects of pre-emptive analgesia where the same intervention is compared when given before or after the nociceptive stimulus, and preoperative analgesia where analgesia is given before surgery and compared with no intervention or with placebo. Administration of analgesia before surgery compared with no intervention or with placebo is known to provide superior analgesia and to reduce pain compared with placebo.[4 24] The appropriate design of a study to detect the pre-emptive effects of an analgesic, if any, has been described[26] and this study was performed in accordance with that design.

We designed this study to eliminate these factors by studying a major procedure associated with consistently high scores in measures of postoperative pain,[27] adhering to the appropriate design for a study of pre-emptive analgesia and using a combined opioid, NSAID and local anaesthetic–analgesic regimen. We also studied the effect on postoperative chronic pain syndrome associated with thoracotomy to determine if the practice of pre-emptive analgesia had any effect on the incidence of this problem.

Patients and methods

The study was approved by the local Ethics Committee and informed written consent was obtained from each subject. We studied 30 subjects undergoing unilateral posterolateral thoracotomy for lobectomy or pneumonectomy. Exclusion criteria included any history of a chronic pain condition, current use of analgesic medications or contraindications to the use of non-steroidal anti-inflammatory drugs. Before operation, all subjects were instructed in the use of patient-controlled analgesia (PCA) and the use of a 100-mm visual analogue scale for reporting of pain, and introduced to the use of blunt tipped 27-gauge dental injection needles for determination of the extent of local anaesthetic block.

	Group Pre	Group Post
Sex (M:F)	12:3	11:4
Age (yr)	61.6 (34–79)	59.8 (30–72)
Weight (kg)	73.7 (9.8)	72.8 (11.3)
Procedure		
(Lobectomy:pneumonectomy: thoracotomy without lung resection)	8:6:1	9:3:3
Side (R:L)	6:9	8:7
Duration of surgery (min)	119 (56)	95 (34)
Duration of postoperative chest drainage (h) (median (range))	48 (17–144)	42 (12–164)

Subjects were premedicated with temazepam 20 mg orally, 1–2 h before operation. Anaesthesia was induced after preoxygenation with propofol 2–3 mg kg^{-1} and atracurium 0.6 mg kg^{-1}. After tracheal intubation with an appropriate double-lumen tube and verification of its position, the lungs were ventilated with 1–5% enflurane and nitrous oxide in oxygen, and an infusion of atracurium 0.5 mg kg^{-1} h^{-1} was commenced. The concentration of enflurane during surgery was varied as required to maintain heart rate and arterial pressure within 20% of pre-induction values. All surgical procedures were performed by the same surgeon in the morning of the same day of the week.

Subjects were allocated randomly using computerized randomization to one of two groups. In group Pre, subjects received morphine 10 mg i.v., diclofenac 75 mg i.m. and intercostal nerve blocks in spaces 2–11 with a total 40 ml of 0.5% bupivacaine with epinephrine 1/200 000 and 8.4% sodium bicarbonate 1 ml which has been shown to increase the duration of intercostal nerve block produced by bupivacaine and epinephrine.[28] In group Post, subjects received dummy i.v. and i.m. injections and a series of dummy intercostal nerve blocks. No other analgesics were administered during surgery. The start of surgery was then delayed for at least 20 min after administration of analgesic or dummy injections to ensure that any analgesic intervention was effective before nociceptive stimulus.

At the end of surgery, subjects in group Pre received dummy i.v. and i.m. injections and a series of dummy intercostal nerve blocks. Subjects in group Post received morphine 10 mg i.v., diclofenac 75 mg i.m. and intercostal nerve blocks with a total of 40 ml of 0.5% bupivacaine with epinephrine 1/200 000 and 8.4% sodium bicarbonate 1 ml. Anaesthesia was maintained for another 20 min before antagonism of neuromuscular block and discontinuation of anaesthesia. All analgesic procedures were performed by a single investigator.

Postoperative management of subjects in both groups was identical. When patients were able to co-operate they gave a visual analogue score for pain and the extent of intercostal nerve block was assessed. If there was an inadequate intercostal nerve block the blocks were repeated. In the event of pain outside the distribution of the intercostal nerves, subjects received increments of morphine 2 mg until they were pain free. Subsequently, subjects administered PCA using morphine 60 mg in 0.9% saline 60 ml (1 mg ml^{-1}) containing metoclopramide 60 mg. The bolus dose was 1 mg, background infusion 0.5 mg h^{-1} and lockout interval 6 min. Diclofenac 50 mg orally was administered every 8 h. Additional boluses of morphine 5 mg were prescribed and administered by nursing staff if the visual analogue score was persistently greater than 40 mm. Intercostal nerve blocks were repeated by the same investigator as previously if a subject was in significant pain (visual analogue score >40 mm), was unable to cough and clear secretions and had no demonstrable remaining intercostal nerve block. Physiotherapy and nursing care were given by the same people to patients in both groups.

Assessments of pain were performed in the recovery area and at 6, 12, 18, 24, 30, 42 and 48 h after operation. On these occasions subjects gave a visual analogue score from 0–100 mm for pain before and after taking a vital capacity breath and the extent of the intercostal nerve block was assessed using a 27-gauge blunt tipped dental injection needle. Ventilatory frequency and arterial oxygen saturation were also noted at these times. Other assessments made were time to first oral intake and duration of chest drainage. All assessments were performed by a single observer who was unaware of the intraoperative analgesic management of the subjects.

After 48 h, PCA was discontinued and analgesia provided with dihydrocodeine 60 mg orally every 4 h as required, morphine 10 mg i.m. every 3 h as required and diclofenac 50 mg orally every 8 h as required. Analgesic consumption during the following week and duration of hospital stay were also noted.

At 6 and 12 months after operation, patients' notes were examined to determine if they were still alive. If so a telephone call was made and subjects were asked about the occurrence of symptoms of post-thoracotomy pain or post-thoracotomy syndrome using the definition of the International Association for the Study of Pain[29] of pain that recurs or persists along a thoracotomy scar at least 2 months after surgery. Specific questions were asked about a burning or aching quality to the discomfort, pain caused or worsened by routine stimuli and delayed or exaggerated responses to routine stimuli. Current analgesic consumption for pain at the site of the thoracotomy was elicited. All of these calls were made by the same blinded observer.

We calculated that this study had a power of 80% to detect differences between groups which would be significant at the 5% level. This calculation was similar to that used in several other studies investigating the presence or absence of pre-emptive analgesia in clinically relevant circumstances.[9, 16, 20] Statistical analysis was performed using the Student's *t* test for normally distributed data and the Mann–Whitney *U* test for skewed data.

Results

The two groups were similar in patient data and operative procedures (table 1).

In all subjects there was an intercostal block from T2 to T11 on the side of surgery in the recovery area. One subject in group Pre and two in group Post required i.v. morphine in the recovery area.

There was no difference between groups in postoperative consumption of morphine by patient-

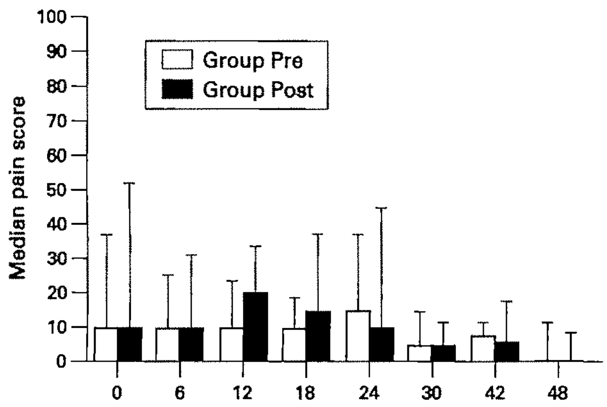

Figure 1 Median visual analogue pain scores in groups Pre and Post at rest during the postoperative period.

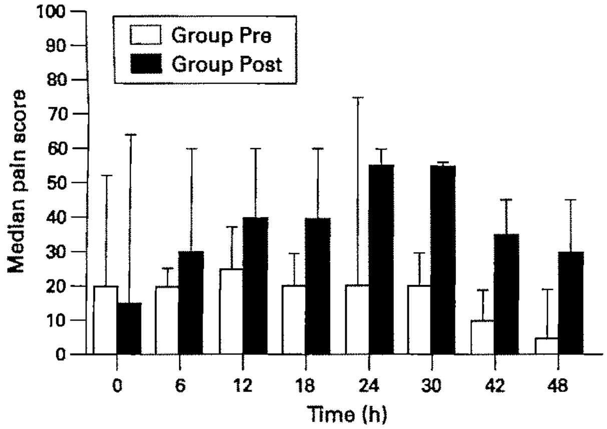

Figure 2 Median visual analogue pain scores in groups Pre and Post during a vital capacity breath during the postoperative period. $P < 0.05$.

Table 2 Requirements for analgesia during postoperative days 2–7 in group Pre and group Post (median (range) number of doses)

	Group Pre	Group Post
Diclofenac	12 (1–19)	12 (6–16)
Dihydrocodeine	7 (1–16)	9 (3–17)
Morphine	0 (0–3)	1 (0–4)

controlled analgesia. Subjects in group Pre consumed a median of 92 (range 50–136) mg and those in group Post 82 (32–128) mg during the first 48 h after operation. Total morphine consumption comprising morphine by patient-controlled analgesia and additional boluses of 5 mg administered by nursing staff was 95 (50–156) mg in group Pre and 82 (32–172) mg in group Post.

There was no difference in visual analogue scores between patients at rest in group Pre and group Post at any of the assessments during the postoperative period (fig. 1).

In group Post, VAS scores during a vital capacity breath were significantly higher ($P < 0.05$) than those in group Pre at all assessments other than in the recovery area and at 6 h after operation (fig. 2). There was a consistent increase in VAS pain scores during a vital capacity breath over the first 36 h after operation in group Post but not in group Pre.

There was no difference between groups in duration of intercostal nerve block. Median duration of detectable block was 27 (range 8–42) h in group Pre and 24 (18–48) h in group Post. Two subjects in group Pre and three in group Post received repeat intercostal nerve injections on the day after surgery.

During the period from 48 h to 7 days after operation, there was no difference between groups in consumption of diclofenac, dihydrocodeine or morphine administered for pain (table 2).

There was no difference between groups in the time taken to first oral fluid intake, with a median of 9 (range 3–25) h in group Pre and 15 (4–22) h in group Post. There was no difference in the time of discharge from hospital (6 (5–14) days in group Pre and 6 (4–8) days in group Post). Two subjects in group Post were excluded from this analysis as they were transferred to other hospitals for management of a bleeding duodenal ulcer and for nursing care, respectively.

At telephone follow-up, two subjects in group Pre and none in group Post described symptoms of post-thoracotomy neuralgia. One subject in group Post was excluded from this analysis because he underwent subsequent lung transplantation.

Discussion

We have found an effect of pre-emptive analgesia on postoperative visual analogue pain scores during the 48 h after operation which was limited to a reduction in VAS pain scores during a vital capacity breath. There were no differences between groups in analgesic consumption, complications or long-term outcome, including the incidence of post-thoracotomy pain. This is despite the use of a model of severe postoperative pain, a design which fulfilled the requirements to detect any pre-emptive analgesic effect and a tightly controlled study design.

Thoracotomy is one of the most painful surgical procedures known, with multiple sources of nociception, including the surgical incision, disruption of ribs and intercostal nerves, pleural inflammation, pulmonary parenchymal damage and the presence of postoperative intercostal drains. The fact that all subjects received both preoperative and postoperative analgesics or placebo fulfils the requirement to detect a pre-emptive analgesic effect. All procedures involved posterolateral thoracotomy performed by the same surgeon while all analgesic interventions were performed by the same consultant anaesthetist and a single blinded observer performed all postoperative assessments to eliminate variability between observers. The similar timing of surgery in both groups implies that events which may have been influenced by ward routines, such as chest drain removal and hospital discharge, should have been influenced in the same way to a similar extent in both groups. The prolonged follow-up of these subjects is unique in studies of pre-emptive analgesia and was designed to detect any difference between groups in the incidence of post-thoracotomy neuralgia. Previous studies have suggested that the incidence and severity of chronic pain after surgery may be modified by the perioperative analgesic regimen[25] but we were unable to find evidence to support this suggestion.

Various reasons why the work performed in animals is not consistently replicated in clinical practice have been suggested. In some of the studies which showed no effect, an appropriate pre-emptive study design was not used with analgesic premedication being administered[15] or analgesic drugs being given before the surgical incision.[13, 17–19, 22] The fact that subjects in this study did not undergo surgery until at least 20 min after the first set of injections and were kept anaesthetized for 20 min after the second set implies that subjects in group Pre had effective clinical analgesia at the start of surgery and subjects in group Post did not emerge from anaesthesia until their analgesic interventions were effective, although it may be that the NSAID component of the analgesic treatments requires more than 20 min to become fully effective.

Several studies have used as models relatively minor surgical procedures such as wisdom teeth extraction,[16] which produce low intensity noxious stimuli that may not generate enough difference between pre-emptive and control groups to demonstrate a clinical effect. In addition, relatively minor surgery may not trigger the altered central processing of sensory inputs which causes subsequent hyperalgesia and allodynia.[30] Conversely, the nociceptive stimulation which is produced during surgery with mixed cutaneous, visceral and muscular components, in addition to emotional or psychological factors, may be more difficult to prevent than that arising from the limited physical and chemical insults used in experimental animals. Clinical postoperative pain is a different entity from nociception inflicted during animal studies and it is not surprising that it is more difficult to demonstrate a genuine pre-emptive effect in this situation compared with animal models. Infusion analgesic regimens which are not titrated to patient request and which produce pain scores of zero may obscure any pre-emptive effect unlike on-demand analgesic regimens where analgesic consumption is determined by the patient and acts as an indicator of the degree of pain or nociception present.

Our analgesic management clearly failed to provide complete ablation of nociceptive stimuli during anaesthesia and surgery, as demonstrated by the requirement for analgesia in the recovery area in several patients, particularly for pain in the shoulder region out with the area of intercostal nerve block. These subjects were not excluded from the analysis because our intention was to compare a clinically relevant pre-emptive analgesic regimen with a clinically relevant non-pre-emptive analgesic regimen accepting that occasionally patients may not have complete analgesia on recovery from anaesthesia. This was despite intercostal nerve blocks, attempting to limit the production of inflammatory mediators with a systemic NSAID and suppressing the central perception of nociception with systemic opioid. Sympathetic and parasympathetic afferents would not have been blocked by our analgesic regimen and neither would the phrenic nerve, which is sensory to the pericardium, mediastinal and diaphragmatic pleura. This fact may also have served to obscure any pre-emptive analgesic effect in group Pre. It would only have been possible to ablate nociceptive stimuli completely in this group by using analgesic regimens which are not clinically relevant, such as very high extradural block or high-dose opioid which would both have presented problems of their own and necessitated postoperative ventilation. Alternatively, the use of interpleural analgesia may have produced a more widespread afferent block from the operated side.

The increase in VAS pain scores during a vital capacity breath in group Post but not in group Pre suggests that sensitization occurred in group Post either peripherally through inflammation, spinally or centrally. The absence of this increase in group Pre may be a manifestation of a pre-emptive analgesic effect.

In summary, this study adds to the growing body of evidence that the effects of pre-emptive analgesia given before surgery are relatively modest in terms of analgesia, analgesic consumption and long-term outcome, and are of limited clinical significance.

Combining propofol with morphine in patient-controlled analgesia to prevent postoperative nausea and vomiting

S. E. Bree, M. J. West, P. A. Taylor and I. G. Kestin

Summary

We have studied the antiemetic effects of propofol when mixed with morphine in a patient-controlled analgesia (PCA) pump after major gynaecological surgery. In a double-blind, randomized, controlled study, 50 women, ASA I or II, received a standardized anaesthetic comprising thiopental, morphine, atracurium, nitrous oxide and oxygen with enflurane, and received postoperative PCA with morphine mixed with either 1% propofol or Ivelip. The PCA bolus was morphine 1 mg with propofol 5 mg or Ivelip 0.5 ml, with a lockout time of 5 min. Postoperative nausea and vomiting (PONV) were assessed by the nursing staff using a four-point ordinal scale and by the patient using a visual analogue scale for 48 h after surgery. The two groups were similar in the potential factors influencing the incidence of PONV. There were no significant differences between the two groups in any of the study measurements of PONV. There were no side effects after propofol. Propofol, when mixed with morphine in this dose combination for PCA, did not decrease the incidence of nausea and vomiting in women undergoing major gynaecological surgery. (*Br. J. Anaesth.* 1998; **80**: 152–154)

Keywords: anaesthetics i.v., propofol; analgesics opioid, morphine; vomiting, nausea; vomiting, postoperative; analgesia, patient-controlled

Postoperative nausea and vomiting (PONV) is one of the more common and distressing causes of morbidity after major surgery. There is a decreased incidence of PONV after propofol.[1–4] Whether propofol has direct antiemetic properties or is merely less emetogenic than other anaesthetic drugs is not known. There has been interest in using subhypnotic doses of propofol both to treat and prevent nausea and vomiting after cancer chemotherapy and surgery.[5–8] Small doses of propofol given in recovery were successful in treating PONV,[7] but the results with postoperative infusion for 24–48 h after surgery were conflicting.[8–11] We have studied the effects of simultaneous administration of propofol and morphine patient-controlled analgesia (PCA) on the incidence of PONV.

Patients and methods

After obtaining approval from the local Ethics Committee, we studied ASA I or II women, aged 30–75 yr, undergoing elective hysterectomy (either abdominal or vaginal). We excluded women weighing more than 100 kg, those who were unable to use patient-controlled analgesia (PCA) and any patient who suffered from epilepsy, ear disease, liver disease, hyperlipidaemia or were receiving drugs with antiemetic properties.

After obtaining written informed consent, all patients were premedicated with temazepam 20–30 mg, 1 h before surgery. Anaesthesia was induced with thiopental, atracurium and morphine 0.2 mg kg^{-1}, and maintained with enflurane (end-tidal 0.5–2%) and 60% nitrous oxide in oxygen. At the end of surgery residual neuromuscular block was antagonized with neostigmine 2.5 mg and glycopyrrolate 0.5 mg. After extubation of the trachea all patients were transferred to the recovery area where they received a PCA (Graseby 3300) consisting of morphine 100 mg mixed in 50 ml of either 1% propofol or 10% Ivelip (10% soya oil, 2.5% glycerol, Clintec).

Derriford Hospital Pharmacy prepared all the study solutions under aseptic conditions and randomized the patients. The stability of morphine, propofol and Ivelip mixtures have been verified previously by HPLC (Dr P. Adams, principal pharmacist, South West Pharmaceutical Quality Control Laboratory, Torbay Hospital, Torquay, personal communication). The patient, anaesthetist, investigators and all nurses were unaware of the contents of the syringe. Another two syringes, each containing 1 ml of either propofol or 10% Ivelip, were supplied by the pharmacy with the appropriate PCA syringe. The first 1-ml bolus was given i.v. by the recovery nurse if the patient complained of nausea or was vomiting. The second syringe was given 5 min later, followed by rescue antiemetic (prochlorperazine 12.5 mg i.m. every 6 h) after another 5 min, as required. The PCA pump was programmed to give morphine 1 mg with either propofol 5 mg or Ivelip 0.5 ml in each successful demand, with a lockout of 5 min. The maximum possible dose of propofol in 1 h was 60 mg. A separate i.v. cannula was used for the PCA. All patients were prescribed oxygen for 24 h and when comfortable were transferred to the ward.

24-48 h	3 (12%)	2 (8%)

At 4-hourly intervals for the first 24 h, and 8-hourly intervals for the second 24 h, the ward nurses recorded PCA demands and doses, nausea scores, episodes of vomiting, antiemetics given and sedation scores.

PONV was recorded as: (1) no nausea or vomiting; (2) nausea alone; (3) nausea with vomiting on one or two occasions; and (4) nausea with vomiting more than twice. Sedation was recorded as: (1) awake; (2) dozing intermittently; (3) mostly sleeping; and (4) only awakens when aroused.

Mean nausea scores for each patient were obtained as the mean of the nursing PONV scores during each 24-h period. In addition, at 24 and 48 h, patients completed two 10-cm visual analogue scales (VAS) for pain and nausea, ranging from none to the worst possible. The amount of morphine and rescue antiemetics given by the nurses were also recorded.

The sample size was chosen to provide a 75% probability of demonstrating a reduction in the incidence of PONV from 60% to 30% when α=0.05. The data were analysed using the Student's t test, Mann–Whitney U test and Fisher's exact test, where appropriate (Instat v2.01, GraphPad; Macintosh System B-7.01), and the level of statistical significance was 5%.

Results

A total of 50 patients were entered into the study. One patient receiving Ivelip was excluded within the first 24 h because of excessive sedation; 25 patients received propofol and 24 received Ivelip. Patient characteristics, duration of anaesthesia and time spent in recovery were similar in both groups (table 1).

The amount of morphine used from the PCA, visual analogue scores for pain and sedation scores were similar in both groups at 24 and 48 h (table 2). There were no significant differences between the two groups in any of the measurements of PONV (table 3).

Discussion

Postoperative nausea and vomiting (PONV) after anaesthesia is less likely with propofol than with other anaesthetic agents, and the magnitude of the reduction depends on the method of administration, time of measurement and baseline incidence of PONV.[4] PONV is least when propofol is used for maintenance and induction of anaesthesia.[4] The action of propofol on dopamine[12-14] and 5HT$_3$ receptors[15] has been investigated, and it seems unlikely that propofol has important activity at these receptors.

There has been interest in using propofol specifically as an antiemetic drug, both as treatment and for prophylaxis.[1] Propofol 10 mg given in recovery was effective in 69% of patients with established PONV (compared with 35% responding to placebo).[7] Schulman, Rockett and Canada reported that a patient with severe refractory PONV was treated successfully with a propofol infusion for 5 days.[16] Gan and colleagues have published their preliminary results using a target-controlled infusion of propofol to treat PONV in recovery.[17] Patients with PONV were given infusions of propofol in increasing doses until treatment was successful or the study limit (a target concentration of 800 ng ml^{-1}) was reached. They found that a target concentration of 405 ng ml^{-1} reduced the verbal nausea score to less than 3 or by 50%. This blood concentration of propofol would normally be obtained with a bolus dose of 10 mg and an infusion of 1 mg kg^{-1} h^{-1}. Details of the patients, anaesthetic techniques and whether a control group were used were not given.[17]

Postoperative infusions of propofol have been tried as prophylaxis against PONV, with conflicting results.[8-11] Patients in the study by Ewalenko and colleagues[8] received an infusion of propofol started in recovery after thyroid surgery. The incidence of PONV was reduced from 65% (in the control group) to 10%,[8] but patients in two other studies did not benefit from using propofol in this way.[9 10] In these three studies,[8-10] propofol was not used for anaesthesia, although Scudieri and colleagues[10] started the subhypnotic infusion of propofol before anaesthesia and surgery. Modest success has been reported in reducing the severity of PONV after intrathecal morphine using a postoperative infusion of propofol for 24 h.[11]

Our premise when starting this study was that by coupling the dose of propofol to that of morphine and by using boluses, which have been shown to be effective, propofol with morphine in a PCA may be an effective technique for both analgesia and antiemesis. In addition, continuous infusion of propofol requires an additional i.v. cannula and syringe driver, and we found this a practical disadvantage in our previous study.[9] The maximum dose of propofol that could be obtained from the PCA pump was 60 mg in 1 h; in practice, the mean propofol dose was much less than this, and the maximum dose of propofol received during any 4-h period by a patient in this study was 180 mg. This is considerably less than would be delivered using the 1-mg kg^{-1} h^{-1} scheme of previous studies of continuous postoperative infusions of propofol.[9 10] The dose of propofol obtained by the patients from the PCA in our study may have been too low if propofol does indeed have antiemetic properties. We chose a propofol bolus dose of 5 mg, which we thought would be safe for the patients to receive on the ward. If we had used a 10-mg bolus, and morphine consumption remained the same, the mean hourly propofol dose would have been 19.6 mg in the first 24 h. This is still less than 1 mg kg^{-1} h^{-1} used previously for prophylaxis of nausea and vomiting after surgery[9 10] or cancer chemotherapy.[5 6] However, the patient who used the most propofol in any 4-h period in this study would have received a mean of 90 mg per hour if a 10-mg propofol bolus had been chosen. She weighed 68 kg, so the dose would have been more than 1 mg kg^{-1} h^{-1} during this time; this may not be safe on a general ward.

In summary, we believe that it is unlikely that propofol will have important postoperative use in treating or avoiding PONV.

Prophylaxis for vomiting by children after tonsillectomy: ondansetron compared with perphenazine

W. M. SPLINTER AND E. J. RHINE

Summary

We have compared the effects of ondansetron and perphenazine on vomiting after tonsillectomy in 216 healthy children, aged 2–12 yr. The study was randomized, stratified, blocked and double blind. Anaesthesia was induced with propofol i.v. or by inhalation of halothane and nitrous oxide. Ondansetron 150 μg kg^{-1} or perphenazine 70 μg kg^{-1} was administered i.v. after induction of anaesthesia in a double-blind manner. Perioperative management of emesis, pain, fluids and patient discharge were standardized. Ondansetron and perphenazine had similar effects on postoperative vomiting (44% *vs* 41%; ondansetron *vs* perphenazine P=0.77). By logistic regression analysis, the only significant predictor of postoperative vomiting was sex, that is males had a greater incidence of vomiting (49% *vs* 35%; P=0.016). In-hospital vomiting was associated with a prolongation of stay in the day-care surgical unit of 7 min per episode of vomiting (P=0.015). We conclude that ondansetron and perphenazine had similar effects on vomiting in children after tonsillectomy in a day-case setting. (*Br. J. Anaesth.* 1998; **80**: 155–158)

Keywords: anaesthesia, paediatric; surgery, otolaryngological; vomiting, antiemetics, ondansetron; vomiting, antiemetics, perphenazine

Vomiting is a common, unpleasant sequel to surgery and anaesthesia and may result in dehydration, important electrolyte disturbances, delayed discharge from hospital and unscheduled admission to hospital.[1–3] Children undergoing tonsillectomy are at particular risk of vomiting, with as many as 71–73% of children vomiting after tonsillectomy.[4] Anaesthetists are searching for cost-effective techniques that may minimize this problem.

Ondansetron and perphenazine are antiemetics that decrease vomiting after tonsillectomy in children.[4 5] For many, ondansetron has become the "gold standard" antiemetic because of its efficacy and minimal side effects compared with alternatives. Unfortunately, ondansetron is expensive. Perphenazine is a phenothiazine with moderate anticholinergic effects, weak to moderate sedative effects and potent antiemetic effects. Compared with ondansetron, perphenazine had similar antiemetic effects and fewer side effects in adults after hysterectomy.[6] We have evaluated the hypothesis that ondansetron and perphenazine have similar effects on vomiting in children after tonsillectomy.

Patients and methods

Healthy children, aged 2–12 yr, undergoing elective tonsillectomy or adenotonsillectomy were enrolled in this randomized, stratified, blocked, double-blind study after obtaining approval from our Ethics Committee. Within the balanced study design, blocks of five patients were stratified according to use of premedication and technique for induction of anaesthesia so that a similar number of patients in each study group received premedication and the two available induction techniques. The children were allocated randomly to receive ondansetron or perphenazine in a double-blind manner. Exclusion criteria included allergy to a study drug, history of sleep apnoea or ASA III or greater.

Patients were permitted to drink clear fluids for up to 3 h before anaesthesia, but did not ingest solid food on the day of surgery. Those children requiring premedication received midazolam 0.5 mg kg^{-1} (maximum dose 15 mg) orally, 20–30 min before induction of anaesthesia. General anaesthesia was induced by inhalation of nitrous oxide and halothane or propofol 2.5–3.5 mg kg^{-1} i.v. Mivacurium 0.25 mg kg^{-1} was administered if a neuromuscular blocking agent was indicated to facilitate tracheal intubation. Ondansetron 150 μg kg^{-1} (maximum dose 8 mg) or perphenazine 70 μg kg^{-1} (maximum dose 5 mg) was administered i.v. in a double-blind manner immediately after induction of anaesthesia. The dose for perphenazine was extrapolated from the adult dose of 5 mg. Anaesthesia was maintained with 0.75–2.0% halothane and 70% nitrous oxide in oxygen. Midazolam 50 μg kg^{-1} (maximum dose 3 mg) i.v. was given if the child had not received it for premedication. (Midazolam was given to all patients because it has been shown to have antiemetic effects in children undergoing tonsillectomy.[7]) All patients received codeine 1.5 mg kg^{-1} i.m. in the right thigh before commencement of surgery. Intraoperative i.v. fluid comprised lactated Ringer's solution at half the calculated deficit during the first hour, plus main-

All cases	47/109 (59)	55/130 (42)

tenance fluids, in addition to replacement of four times the estimated blood loss with crystalloids.

Management of postoperative emesis, pain and fluids was standardized. Vomiting was defined as the forceful expulsion of liquid gastric contents. Retching and nausea were not considered vomiting. Nursing staff and parents were aware of this definition of vomiting. Nursing staff recorded vomiting in the charts, which is standard practice in our hospital. Patients who vomited twice in hospital received dimenhydrinate 1 mg kg^{-1} i.v. Parents were contacted 24 h after surgery by a research assistant to ascertain the number of times their child vomited after discharge from hospital and what the parents had done in response to the vomiting. Pain in the post-anaesthesia recovery room (PAR) was treated with morphine 50 µg kg^{-1} i.v., while subsequent pain was treated with acetaminophen or codeine, or both, in the day-case surgical unit (DCSU) and at home. I.v. fluid comprised lactated Ringer's solution at twice maintenance rates in the PAR and DCSU. Patients were encouraged, but not coerced, to drink clear fluids in the DCSU before discharge. Patients were discharged following a recommended hospital policy of a minimum 4-h stay in the DCSU and after ingestion of clear fluids.

Continuous, normally distributed data, such as patient age, were compared using one-way ANOVA, and continuous, non-normally distributed data, such as length of stay in the DCSU, were compared using the Mann–Whitney *U* test. Binomial data, such as incidence of vomiting, were compared using chi-square analysis and Fisher's exact test, where appropriate. Logistic regression analysis was used to detect if factors such as study drug, age, weight, in-hospital analgesics, premedication, use of neuromuscular blocking agents, operative time, estimated intraoperative blood loss and induction technique were significant predictors of vomiting. Stepwise linear regression analysis was used to assess the effect of study group, in-hospital vomiting, age, premedication and induction technique on length of stay in the DCSU. Sample size was determined by assuming that the acceptable difference in vomiting was 20%. The alpha error was set at 0.05 (two-sided) and type II error was at 0.20. The projected sample size was 110 patients per group after consideration of potential dropouts.

Results

Over a period of 6 months, 220 patients were enrolled. Four patients were subsequently excluded because of major study violations. The groups were similar after stratification and blocking of patients (table 1) and they had similar characteristics (table 2). Mivacurium was administered to 86 patients in the ondansetron group and to 83 patients in the perphenazine group. No patient required antagonism of neuromuscular block. Duration of stay in the PAR was similar in the two groups (mean 46 min *vs* 47 min for the ondansetron and perphenazine groups, respectively) but in the DCSU, ondansetron-treated patients had a briefer stay (median 235 (range 165–305) min *vs* 240 (175–430) min; ondansetron *vs* perphenazine, P=0.007). Analgesic use in hospital was similar. In the ondansetron group, four patients received morphine in the PAR and 108 patients received codeine in the DCSU, while in the perphenazine group, seven patients received morphine in the PAR and 107 patients received codeine in the DCSU.

Episodes of vomiting per patient ranged from 0 to 11. Fifteen patients in the ondansetron group vomited three or more times, while 19 patients in the perphenazine group vomited three or more times. The study groups had a similar incidence of vomiting (table 3). By logistic regression analysis, the sex of the child was a significant (P=0.013) predictor of postoperative vomiting, with 49% of males and 35% of females vomiting. Other potential predictors (study group, age, weight, induction technique, premedication, duration of anaesthesia, estimated intraoperative blood loss, use of neuromuscular blocking agents and use of in-hospital postoperative opioids) of vomiting were not significant (table 4). Patients who vomited twice while in hospital received a rescue antiemetic (dimenhydrinate) which was given to four patients in the ondansetron group and to seven patients in the perphenazine group.

Six patients were admitted or readmitted to hospital after discharge, five of whom were in the ondansetron group. Four of these patients were admitted for surgical reasons: bleeding (n=3) or

Table 2 Patient and surgical data (mean (SD), median (range) or number)

Group	n	Age (yr) (mean (range))	Weight (kg)	Length of anaesthesia (min)	Blood loss (ml)	Sex (M/F)
Ondansetron	109	7.1 (2–12.5)	29 (15)	31 (11)	15 (0–225)	49/60
Perphenazine	107	6.8 (2–12.8)	26 (12)	32 (13)	15 (0–220)	49/58

refusing to drink (n=1). One patient in the ondansetron group required in-hospital management of emesis and one patient was admitted for management of exacerbation of asthma.

Duration of stay in the DCSU was affected significantly by two factors: (1) in-hospital vomiting (P=0.01) and (2) study drug (P=0.02). Each episode of in-hospital vomiting prolonged DCSU stay by 7 min. Patients in the perphenazine group stayed in the DCSU for an average of 7 min longer than patients in the ondansetron group. No adverse events, such as extrapyramidal symptoms or allergic reactions, possibly attributable to ondansetron or perphenazine, were observed or reported by the nursing staff or parents.

Discussion

Ondansetron and perphenazine were observed to have similar effects on the incidence of vomiting in children after tonsillectomy. These similarities in the antiemetic effect were noted in hospital and after discharge. The incidence of vomiting after tonsillectomy was similar to that observed in previous investigations,[4 5 8] but greater than that reported by van den Berg.[9] Although both drugs decreased the incidence of vomiting compared with placebo, the incidence of emesis after prophylactic treatment was still high in this study. Ideally, the incidence of vomiting should be less than the 41% rate noted. Also, a decrease in the use of rescue antiemetics and elimination of the instances where children have numerous episodes of vomiting would be desirable. In addition, the incidence of vomiting on the day after surgery (25–26%) is of concern.

We used a blocked, stratified design to permit both control and flexibility. Patients were enrolled into this study before the parents and their child's anaesthetist had come to a decision as to premedication and the anaesthesia induction technique. The blocked and stratified approach leads to a balanced design, which simplifies inter-group comparisons, while flexibility in choice of premedication and induction technique optimizes clinical management.

Adverse effects with a single, therapeutic dose of ondansetron or perphenazine are extremely rare and generally minor. In Desilva and colleagues's study in adults,[6] only patients who received perphenazine were free of adverse side effects. Perphenazine is a phenothiazine, a class of drugs which have a high therapeutic index and "are remarkably safe agents".[10] Major adverse side effects after a single dose of ondansetron are rare, and there is only one report of dyskinesia after a single dose of perphenazine.[11] Although there were no adverse events caused by perphenazine during this and previous studies,[5 12] much larger sample sizes would be required to evaluate accurately the incidence of adverse effects after perphenazine in children.

The prophylactic antiemetics used in this study were dissimilar with respect to cost. The ondansetron dose for a 20-kg child (3 mg) costs $12.90 Canadian, while perphenazine costs only $0.81 Canadian for the treatment of a 20-kg patient. Treatment of emesis by nursing staff and family, delayed hospital discharge, unscheduled admission and mental costs to the patient and family also add to the cost of care. Of note, in this study those patients in the perphenazine-treated group had a slight delay in discharge (7 min) from the day-case surgical unit compared with the ondansetron group. Unfortunately, we are not able to calculate the cost of such delays within our health care system.

The dose of perphenazine was based on the 5-mg dose used in adult investigations. A larger dose (8 mg) has been noted to increase drowsiness among adult oncology patients.[13] There are, to the best of our knowledge, no dose–response curves for the antiemetic effect of this drug in the perioperative setting in adults or children. While the dose used in our study has been shown previously to be effective, it is not necessarily the optimal dose. The ondansetron dose is based on previous studies in children in a perioperative setting.[4 14]

The aetiology of vomiting after tonsillectomy is unknown and probably multifactorial in origin. Surgical techniques which minimize blood loss may be as effective as the use of antiemetics in attempting to decrease vomiting after tonsillectomy.

The sex of the child was identified as a significant predictor of postoperative vomiting by logistic regression analysis. This is, to the best of our knowledge, the first report that male children vomit more than female children after anaesthesia–surgery and is probably a spurious finding. It is not expected that future studies will support this observation. With almost identical male to female ratios in the two study groups, the difference in vomiting according to the child's sex had no effect on our results.

In summary, ondansetron and perphenazine had similar effects on vomiting in children after tonsillectomy. However, the observed incidence of vomiting was unacceptably high (41–44%), especially on the day after surgery (25–26%).

Effects of preinduction and intraoperative warming during major laparotomy†

M. Bock, J. Muller, A. Bach, H. Bohrer, E. Martin and J. Motsch

Summary

We have investigated the influence of active warming before and during operation on blood loss, transfusion requirements, duration of stay in the post-anaesthesia care unit (PACU) and perioperative costs in 40 patients undergoing major abdominal surgery. Patients were allocated randomly to one of two groups: in the study group ($n = 20$), patients were actively warmed using forced air for 30 min before induction of general anaesthesia and during anaesthesia. Passive protection against heat loss consisted of circulating water mattresses, blankets and fluid warming devices, and was used both in the active warming group and in the control group ($n = 20$). At the end of surgery the change in core temperature was significantly less in the group of actively warmed patients (0.5 (SD 0.8) °C *vs* 1.5 (0.8) °C; $P \leq 0.01$). Blood loss and transfusion requirements were less in the actively warmed patients, who had a shorter duration of stay in the PACU (94 (SD 42) min *vs* 217 (169) min; $P \leq 0.01$) and a 24 % reduction in total anaesthetic costs. (*Br. J. Anaesth.* 1998; **80**: 159–163)

Keywords: surgery, abdominal; hypothermia; temperature, effects; temperature, monitoring; equipment, warming devices

Central body temperature decreases after induction of general anaesthesia as a result of reduced metabolic heat production and redistribution of heat from the central to peripheral compartments.[1] During laparotomy, heat loss may also be increased because the large surface of the intestine is exposed to the relatively cold environment of the operating room. These findings are relevant because intraoperative hypothermia is associated with an increased rate of postoperative myocardial ischaemia,[2] increased plasma concentrations of catecholamines[3] and an increased rate of postoperative wound infection.[4] Moreover, in patients undergoing total hip replacement, blood loss and transfusion requirements were reduced when central body temperature was kept normal.[5]

During hip arthroplasty, intraoperative hypothermia was prevented by preoperative warming with an electric warming blanket for 90 min.[6] Heat loss in the central body compartment after induction of general anaesthesia may be minimized by active warming of the arms and legs for 30 min.[7] Conflicting results on the effect of central body temperature on duration of stay in the post-anaesthesia care unit (PACU) have been reported.[8 9] As these findings imply that hypothermia may be associated with increased perioperative costs, we investigated if warming for 30 min before induction of anaesthesia combined with intraoperative warming with forced air prevents hypothermia during major abdominal surgery. Additionally, intraoperative blood loss, time to discharge from the PACU and total costs of perioperative management were compared with a control group who received conventional treatment of hypothermia, consisting of fluid warming devices, circulating water mattresses, cotton blankets and postoperative radiant warming.

Patients and methods

After obtaining approval from the local Ethics Committee and written informed consent, we studied 40 patients undergoing major abdominal surgery, allocated randomly to receive either passive isolation against hypothermia with fluid warming devices, circulating water mattresses, two layers of blankets and postoperative radiant warming, or additional active warming of the upper body using forced air, beginning 30 min before induction of general anaesthesia and during anaesthesia.

During a 1-yr period from November 1995 until October 1996, ASA I–III patients undergoing major abdominal surgery for cancer or inflammatory bowel disease were included. In one additional patient, a gastrojejunostomy was performed because of annular pancreas (table 1). All surgical procedures were performed via a median laparotomy, and surgery lasted for more than 2 h. Patients undergoing surgery of the biliary tract, liver, pancreatic surgery or gastrectomy were excluded, as were those who underwent preoperative radiotherapy or suffered from recurrent rectal cancer because of the greater risk of blood loss. No patient showed signs of bowel obstruction or acute onset of inflammatory bowel disease. Patients did not suffer from diabetes mellitus, thyroid disease, autonomic dysfunction, Cushing's syndrome, peripheral

vascular disease, platelet dysfunction or any other coagulopathy, or had a history of smoking more than 20 cigarettes per day for more than 5 yr or treatment for arterial hypertension. Patients' weights were within 20% of ideal body weight. On arrival in the preoperative holding area, tympanic membrane temperature was measured, and patients with a temperature greater than 37.5 °C or less than 36.5 °C were excluded.

STUDY DESIGN

Passive prevention of hypothermia included covering the patient's body and extremities with two layers of blankets and the use of circulating water mattresses (temperature set at 39 °C) and fluid warming devices for infusions. Active warming was provided by the Warm Touch System (Mallinckrodt Medical GmbH, Hennef/Sieg, Germany) set at the highest flow rate and in the temperature range 40–42 °C. When the system switched to the range below this, the temperature of the forced air was reset to 40–42 °C. Ambient room temperature was maintained at approximately 22 °C during the preinduction period and during anaesthesia.

On the evening before surgery, the bowel was cleaned with a standard electrolyte solution. Ten minutes before arrival in the holding area, patients were premedicated with midazolam 7.5 mg orally. After haemodynamic and temperature monitoring had been established, the patient's abdomen and legs were covered with two layers of blankets. The arms and chest of those patients receiving preoperative active warming were warmed using forced air, whereas in the control group the arms and chest were covered with blankets. Thirty minutes later, general anaesthesia was induced with fentanyl 2–4 $\mu g\ kg^{-1}$, thiopental 3–5 mg kg^{-1} and atracurium 0.5 mg kg^{-1} or cisatracurium 0.1 mg kg^{-1}. The trachea was intubated, a central venous catheter was inserted into the right internal jugular vein and a 14-gauge cannula into a forearm vein. Warmed fluids were provided via this cannula. The central venous catheter was used for drug administration and for measurement of central venous pressure. When considered necessary, a 20-gauge cannula for continuous measurement of arterial pressure was inserted into the right radial artery. Anaesthesia was maintained using fentanyl, isoflurane (maximum end-tidal volume 1.0 MAC) and nitrous oxide in 70% oxygen. Fresh gas flow was kept constant at 3.0 litre min^{-1}.

Fluid replacement was guided by central venous pressure. A core temperature of less than 35 °C or significant peripheral vasoconstriction for more than 2 h were judged as criteria for maintaining mechanical ventilation after operation. The criteria for tracheal extubation after mechanical ventilation in the PACU were: central body temperature >36.0 °C, absence of significant peripheral vasoconstriction, and heart rate and arterial pressure within ± 20% of baseline. In the postoperative phase, radiant heat was used to rewarm hypothermic patients.

MEASUREMENTS

Arterial pressure was measured non-invasively via oscillometry; in a few patients it was also recorded via invasive arterial pressure measurement when indicated medically. An electronic thermocouple (Mallinckrodt Medical) was used to record tympanic membrane temperature, which was considered to reflect central body temperature.[1] Skin surface temperatures were measured by thermocouples placed on the middle of the forearm and on the tip of the ipsilateral middle finger; temperatures were obtained from the arm that was not used for indirect measurement of arterial pressure. A difference between central and peripheral temperatures of more than 4.0 °C was considered to indicate significant vasoconstriction.

During operation, arterial pressure, heart rate, peripheral oxygen saturation, end-tidal carbon dioxide and isoflurane concentrations, and temperatures were recorded at 15-min intervals. Central venous pressure was measured at 30-min intervals, and central venous or, if available, arterial blood-gas samples were obtained every 60 min. After operation, temperatures were recorded at 30-min intervals until normothermia was achieved. On arrival in the PACU, blood samples were obtained for coagulation tests and blood cell counts, and to measure blood-gas tensions and serum concentrations of electrolytes, creatinine and urea. Laboratory analyses were repeated on the first postoperative day. For analysis of arterial and central venous blood-gas tensions, the Ciba Corning 288 (Ciba Corning, Fernwald, Germany) analyser was used.

Blood loss was estimated by an independent anaesthetist who was not involved in the study and who took care of the patient during surgery or during the patient's stay in the PACU. The indication for transfusion of packed red blood cells or fresh frozen plasma was confirmed by the supervising staff anaesthetist who was also not involved in the study. Thus the anaesthetist in charge was always blinded to the fact that the amount of blood loss and transfusion requirements were part of the study. The presence or absence of shivering was determined by the anaesthetist in charge on the PACU who was blinded to the study. The time the patient was ready to be discharged from the PACU was set retrospectively by a blinded observer using a modified Aldrete and Kroulik scoring system.[10] A core temperature of more than 36.0 °C and a score of 14 points was regarded as a criterion for discharge (table 2).

The costs of perioperative management were calculated with respect to the salaries and costs for the University of Heidelberg in August 1996. For preinduction warming, we calculated a nurse-to-patient ratio of 1:4; the costs of treating patients in the control group before induction of anaesthesia were calculated as zero. During surgery, an anaesthetist-to-patient ratio of 1:1 and a nurse-to-patient ratio of 1:2 was assumed. In the PACU, the anaesthetist-to-patient ratio was 1:10. For a patient who required

mechanical ventilation in the PACU, the nurse-to-patient ratio was regarded as 1:1, and for a spontaneously breathing patient in the PACU it was 1:3. A cost of £14.30 sterling was calculated for an upper body layer of the Warm Touch System. No costs were calculated for the ventilator of the Warm Touch System or for the radiant heater because both devices were already present in our department. The costs calculated for each patient comprised the salaries for the anaesthetist and nurse assisting him and the costs for anaesthetic equipment, such as venous catheters, tracheal tubes, etc., and the medical treatment the patient required. The costs for isoflurane and nitrous oxide were not taken into consideration. An exchange rate of £1 to 2.8 German marks was assumed for calculation of perioperative costs.

DATA ANALYSIS

Time-dependent results were evaluated using analysis of variance (ANOVA) with *post hoc* Scheffé's test. Results in the two treatment groups were compared by unpaired, two-tailed *t* tests. Data are presented as mean (SD).

Results

Patient characteristics, duration of surgery and anaesthetics are given in table 3. There were no differences between the two groups. After operation, one patient in the control group was admitted to the intensive care unit which was not controlled by anaesthetists. Consequently, this patient was excluded from the calculation of perioperative costs. Duration of stay in the PACU was not investigated in this patient because postoperative treatment differed.

Before operation, central body temperature was not altered in either group. During the preinduction period, central body temperature did not differ significantly between the two groups. From 15 min after intubation until the end of surgery, central body temperature was higher in the prewarmed group ($P \leq 0.01$) (fig. 1) and remained higher in this group for the first 180 min after arrival in the PACU ($P \leq 0.01$ for the first 150 min; $P \leq 0.05$ for the following 30 min). At the end of surgery and during the first hour in the PACU, 12 of 20 patients in the control group showed significant vasoconstriction, whereas vasoconstriction was detectable in only four of 20 patients in the prewarmed group. On arrival in the PACU, seven patients in the control group showed signs of shivering, and six additional patients underwent mechanical ventilation because of hypothermia. In all patients in the prewarmed group, the trachea was extubated immediately after surgery. Only one of these patients showed shivering in the PACU.

Intraoperative blood loss was significantly less in the normothermic group (635 (507) ml *vs* 1070 (803) ml; $P \leq 0.05$). During operation, only one patient in the study group received 2 u. of packed red blood cells, while in the control group six patients received blood products. By the morning after surgery, packed red blood cells or fresh frozen plasma had been transfused to two study patients. However, a total of nine control patients received blood products by the first morning after surgery. Expressed in millilitre per patient, warmed patients were given significantly less blood products on admission to the PACU (30 (134) *vs* 240 (432) ml/patient; $P \leq 0.05$) and by the morning after surgery (95 (293) *vs* 502 (754) ml/patient; $P \leq 0.05$).

There were no significant differences in partial thromboplastin time or prothrombin time between the two groups before operation, on admission to the PACU, 12 h after operation or on the first morning after operation. Among warmed patients, platelet count decreased from 303 000 (100 000) µl^{-1} before operation and 296 000 (109 000) µl^{-1} on admission to the PACU, to 266 000 (60 000) µl^{-1} 12 h after the end of operation. On the morning after surgery, platelet count was 234 000 (80 000) µl^{-1} in this group. In the control group, platelet count decreased from 288 000 (83 000) µl^{-1} before operation and 257 000 (77 000) µl^{-1} to 218 000 (54 000) µl^{-1} 12 h after operation and remained constant for the next 24 h. There was no significant difference between the two groups, but using a two-tailed paired *t* test, the level of significance was 0.065 at 12 h after operation.

After 94 (42) min, prewarmed patients were ready to be discharged from the PACU compared with 217 (169) min in the control group ($P \leq 0.01$). The costs of treatment from the beginning of preinduction warming until discharge from the PACU were £408 (105) for an aggressively warmed patient and £534 (250) for a control patient ($P \leq 0.05$). Thus 24% of the costs for the anaesthetic treatment could be saved by maintenance of normothermia. Preinduction warming contributed to 4.6 (1.3)% of total costs.

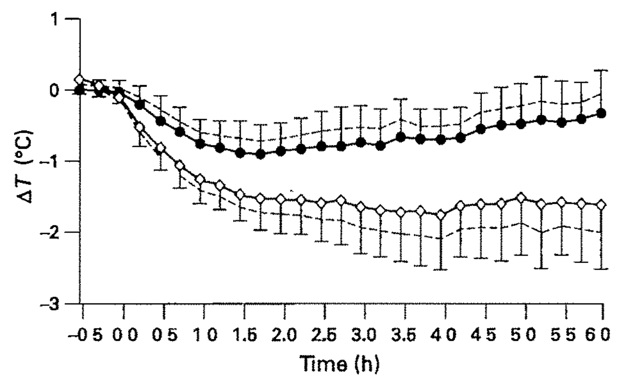

Figure 1 Change in core temperature (ΔT) during the preinduction period and anaesthesia in the actively warmed patients (closed symbols) and in the control group (open symbols). Time zero = induction of general anaesthesia. Data are mean (SD) (95% confidence interval of the mean). $P < 0.01$ from 0.25 h to 6 h.

Discussion

Our major finding was that maintenance of normothermia reduced the total costs for anaesthetic treatment overall by 24% during major abdominal surgery. This was mainly because of a shortened stay in the PACU, lower incidence of postoperative mechanical ventilation and reduced perioperative blood loss, resulting in fewer transfusion requirements in normothermic patients.

Our study supports the findings of Schmied and co-workers on the effect of core hypothermia on blood loss and transfusion requirements during total hip arthroplasty.[5] We did not include such a detailed haemodilution and transfusion procedure in our study because much greater blood loss could be tolerated by the younger patients undergoing abdominal surgery. In common with Schmied and co-workers,[5] we did not observe any significant differences in prothrombin time or partial thromboplastin time between groups. One reason might be that the laboratory investigations were performed at a temperature of 37 °C and a reversible coagulopathy induced by hypothermia may only be detected when clotting tests are performed at the patient's central body temperature.[11] [12] In contrast, some patients received fresh frozen plasma in the control group when coagulopathy was observed clinically, whereas among normothermic patients fresh frozen plasma was not given. The assumption that hypothermia produces a clinically relevant coagulopathy in abdominal surgery was also supported by a study on the effects of hypothermia on wound infection and duration of hospitalization.[4] Normothermic patients required less units of red blood cells than hypothermic patients during abdominal surgery lasting approximately 3 h. In our study, normothermic patients had a slight, but non-significant, higher platelet count 12 h after operation. This may also indicate a clinically relevant coagulopathy in hypothermic patients.

In contrast with our results, hypothermia was found to have no influence on duration of stay in the PACU in children recovering from peripheral surgery.[8] However, that study was not randomized, and patients and surgical procedures were different from those in our investigation. The assumption that hypothermia prolongs post-anaesthetic recovery has recently been proved in a randomized prospective study[9] which concurs with our data. Unlike this investigation, we included central body temperature as a criterion for fitness of discharge from the PACU, as some hypothermic patients underwent mechanical ventilation when they arrived in the PACU. In contrast with the study by Lehnhardt and co-workers[9] however, hypothermia was treated after operation in our study.

The estimated salary of a nurse taking care of four patients in a holding area and the cost of the upper body layer of the Warm Touch System contributed to 4.6% of the costs of total perioperative anaesthetic management during the day of surgery. Considering all aspects, however, the costs of perioperative management for each patient were significantly lower in the actively prewarmed group. Thus the 24% reduction in costs for each actively warmed patient represents a large economic impact compared with the cost of approximately £1430 for the ventilator of an active warming device. These results are new and have been confirmed only indirectly by other studies which showed complications associated with mild intra- and postoperative hypothermia. Thus maintenance of intraoperative normothermia has been shown indirectly to reduce the costs of hospitalization by incurring a lower incidence of wound infections and a shorter duration of hospitalization,[4] shorter duration in the PACU,[9] reduced transfusion requirements[5] and a lower incidence of myocardial ischemia.[2] However, our study is the first to have directly evaluated the economic benefits of intraoperative normothermia for an anaesthesia department.

The reduction in total costs of perioperative treatment of a single patient produces an economic benefit for the anaesthetic department as a whole. This would appear to contradict a computer simulation of economic management of a PACU.[13] In that investigation, the distribution of admissions to PACU was found to be the major determinant of PACU costs, whereas the time of fitness for discharge was of minor economic importance. However, in that analysis, the PACU investigated was solely for outpatients, that is those recovering from minor surgery. Our PACU, however, provides care for patients recovering from outpatient surgery and for those undergoing major abdominal or vascular surgery, including the opportunity for postoperative mechanical ventilation. The costs of supplies, medication and transfusion products are thus likely to be higher in our PACU than in a PACU for outpatient surgery where they contribute to only 2% of the total costs.[13] However, the costs of loans are also the major determinant for the total costs in our PACU. Contrary to the study by Dexter and Tinker,[13] our PACU is also used during the night. Thus a smaller number of nurses have to work during the night shift in our PACU if patients are ready to be discharged earlier in the evening after maintenance of perioperative normothermia.

In summary, maintenance of intraoperative core normothermia helped to reduce blood loss and save blood products. Furthermore, duration of stay in the PACU was prolonged in hypothermic patients, even though hypothermia was treated in the PACU. The costs of perioperative management were lower in patients who remained normothermic although they had to be supervised during the preinduction warming period.

Relationship between cardioventilatory coupling and respiratory sinus arrhythmia

D. C. GALLETLY AND P. D. LARSEN

Summary

Recent studies have suggested a role for respiratory sinus arrhythmia in improving pulmonary gas transfer. However, the physiological role of cardioventilatory coupling is unknown. We have tested the hypothesis that cardioventilatory coupling aligns heart beats at positions of the ventilatory cycle where they are maximally affected by respiratory sinus arrhythmia (RSA). In 15 anaesthetized, spontaneously breathing subjects, we recorded continuously the timing of inspiration and the ECG. We then plotted the change in RR interval which occurred, as a result of RSA, after onset of inspiration (RSA plot). By comparing these RSA plots with the distribution of heart beats during the ventilatory cycle, we were able to examine the positioning of heart beats relative to acceleration of heart rate as a result of RSA. In all but two subjects we observed that during periods of strong cardioventilatory coupling, heart beats occurred at positions in the ventilatory cycle where they were maximally affected by RSA. In the presence of strong coupling, the shortest possible RR interval occurred during late inspiration, the longest possible RR interval occurred immediately before the start of inspiration. We suggest that cardioventilatory coupling may have a physiological role in optimizing RSA, perhaps to improve cardiopulmonary performance during sleep. (*Br. J. Anaesth.* 1998; **80**: 164–168)

Keywords: heart, heart rate; heart, arrhythmia; monitoring, electrocardiography; cardiorespiratory system, effects

Respiratory sinus arrhythmia (RSA) is the variation in heart beat interval with respiration. Since its description by Carl Ludwig in 1847 the mechanism of RSA has been the subject of considerable research interest. Currently it is believed that RSA results from modulation of vagal efferent activity to the cardiac sinus node through gating of excitatory input to the vagal motor neurones from lung inflation afferents.[1] Inspiration is accompanied by vagal withdrawal and a corresponding increase in heart rate, expiration is accompanied by increased vagal tone and a decrease in heart rate. The magnitude of RSA varies according to the degree of vagal tone and may be reduced by standing, age and administration of drugs which interfere with muscarinic cholinergic receptors.[2]

A separate interaction between heart beats and respiration is cardioventilatory coupling (CVC), an entrainment phenomena in which ventilation and heart beats become synchronized in whole number ratios and heart beats appear to fall in constant timing relationship with inspiratory onset. Coupling is seen best under conditions of low arousal: sleep, sedation and general anaesthesia. The synchronization of gill movements to heart beats was first described in fish by Schoenlein in 1895,[3] the coupling of ventilation to heart beats in mammalian species by Coleman in 1921[4] and in humans by Galli in 1924.[5]

The mechanism of CVC is thought to be triggering of inspiratory timing by arterial or intracranial pressor receptor afferents.[5] Unlike RSA which is the modulation of cardiac timing by pulmonary afferent information, CVC is a modulation of inspiratory timing by haemodynamic afferent information.

Despite their important effects on governing the interaction between breathing and heart rate, the link between CVC and RSA is not known. However, as coupling aligns inspiratory onset to heart beats, then it must also position heart beats where they are subjected to varying degrees of vagal modulation from RSA. Although the physiological role of CVC is not known, there is a general belief that RSA may help stabilize cardiovascular variables in the face of fluctuating intrathoracic pressure[6] and recent work suggests that it may improve pulmonary oxygenation.[7] If RSA has a role in improving cardiopulmonary performance, then the positioning of heart beats where they are maximally affected by RSA could have some physiological benefit. In this study, we have examined the hypothesis that CVC aligns heart beats relative to inspiratory onset such that the inter-beat interval is maximally affected by RSA.

Patients and methods

After obtaining Ethics Committee approval, we obtained data from 20 consenting, adult patients undergoing elective surgical procedures under general anaesthesia. None was receiving regular medications or had evidence of cardiorespiratory disease.

Anaesthesia was induced with propofol 2–2.5 mg kg^{-1} and maintained by spontaneous inhalation of 1–1.5% isoflurane and 66% nitrous oxide in oxygen. After induction, a laryngeal mask airway was

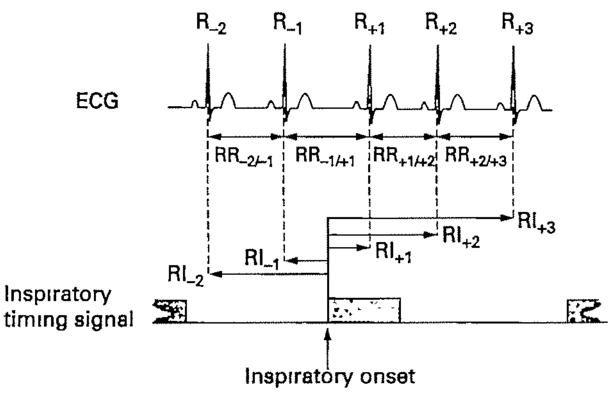

Figure 1 Schematic representation of ECG and inspiratory timing signals. From these signals the time interval from the R wave to the following onset of inspiration (RI_{-1}, RI_{-2}) and the preceding onset of inspiration (RI_{+1}, RI_{+2}, RI_{+3}) are calculated. The R waves of the ECG are denoted relative to the onset of inspiration. R waves preceding inspiration are designated negative subscripts (thus R_{-1} is the R wave immediately before onset of inspiration). R waves after inspiration are given positive subscripts (thus R_{+1} is the R wave immediately after inspiration). RR intervals are denoted by the subscripts of the two bounding R waves: $RR_{-1/+1}$ is the RR interval between the R wave which immediately precedes inspiration to the R wave which immediately follows.

inserted. The last 10 patients received an opioid to aid mask insertion: five received fentanyl 50–100 µg and five morphine 5–10 mg. All data recordings were made after opioid administration but before the onset of surgery.

We recorded continuously the ECG (lead CM_5, Corometrics Neo-Trak 502) and the timing of inspiratory onset. Inspiratory timing was measured by incorporating a Ruben non-return valve into the anaesthetic breathing system. The valve was modified by addition of a photodetector and light beam across the path of the valve shuttle which generated a 1.5-V square wave signal while the valve was open (from the start of inspiration to the end of inspiration). Using this method of inspiratory timing, a small delay may be expected from the onset of inspiratory airflow until opening of the valve shuttle. Measured inspiration therefore falls a little after true inspiratory onset and this delay may vary depending on inspiratory flow patterns. As this delay is small however and equally affects the RSA curve, RI_{+1} and RI_{+2} (see below), and by confining analysis of these measurements to within-subject comparisons, we believe the delay is unlikely to affect the conclusions of our study.

For a minimum of 20 min, ECG and photodetector output were recorded using a 16-bit ADC board (NB-MIO-16, National Instruments), on a Macintosh IIcx personal computer at a sampling rate of 500 Hz.

ANALYSIS

Cardioventilatory coupling

Cardioventilatory coupling was assessed by measuring the time of each R wave peak from the ECG and the time of each inspiratory onset. We then determined the time interval between each R wave and the immediately following, and preceding, inspiratory onset (RI intervals). RI intervals and R waves for heart beats preceding the inspiration were given a negative subscript and those after inspiration were given a positive subscript: R_{-1} for the beat preceding the inspiration and R_{+1}, R_{+2} etc for consecutive beats after inspiration. RR intervals were given a subscript according to the their bounding R waves: $RR_{-1/+1}$ for the interval between R_{-1} and R_{+1}. This nomenclature is explained in figure 1. $RI_{\pm}$ intervals were plotted against time of R wave occurrence (RI plot). Coupling of heart beats and ventilation is revealed in these plots as horizontal banding, in which values of $RI_{\pm}$ remain constant over time.

Because the degree and pattern of cardioventilatory coupling varies in any individual over time,[8] RI plots commonly show periods of poor coupling where heart beats occur in no fixed relationship to inspiratory onset and periods of stronger synchronous coupling where heart beats occur, to varying degrees, in constant timing relationship to inspiratory onset. In part, this patterning varies according to the degree to which heart rate and ventilatory rate are in whole number ratio.

RSA plots

Shortening of RR interval, which occurs after the onset of inspiration as a result of RSA, was displayed graphically by plotting, for each R wave, the normalized preceding RR interval (duration of the preceding RR interval divided by the mean RR interval; the mean being calculated empirically from a window 10 beats on each side of the interval under examination) against the time at which that heart beat decreased after the onset of inspiration. Mean values of normalized RR were then obtained for each 0.1-s interval after inspiratory onset and the curve of respiratory sinus arrhythmia (RSA plot) constructed by interpolating these points. These RSA plots were established from those portions of the RI time series in which coupling was least apparent (weak or absent coupling), during which time heart beats occurred at all phases of the ventilatory cycle and the full extent of the RSA curve could be seen. From these plots we then measured the time from inspiratory onset to: (a) the time at which RR interval acceleration began; and (b) the nadir of the RSA curve (fig. 2).

From segments of the RI plot which showed strongest coupling (heart beats and ventilations were in reasonable synchrony for periods of longer than 50 breaths) we constructed histograms of R wave distribution after inspiratory onset. We then superimposed these plots and the previously constructed RSA plots to determine where, within the RSA curve, groupings of heart beats occurred during cardioventilatory coupling (fig. 3). The mean time to these R wave groupings from inspiratory onset (RI_{+1}, RI_{+2} ....) was calculated and compared with the onset of acceleration and nadir points of the RSA curve.

All data acquisition and raw data analysis were performed using software developed in LabView 2 (National Instruments) and purpose written by the authors. Statistical analysis was performed using Statview 4 on a Macintosh LCIII personal computer.

Results

Of the 20 subjects, 15 had RI plots suitable for analysis (six males, nine females, mean age 30.7 (range

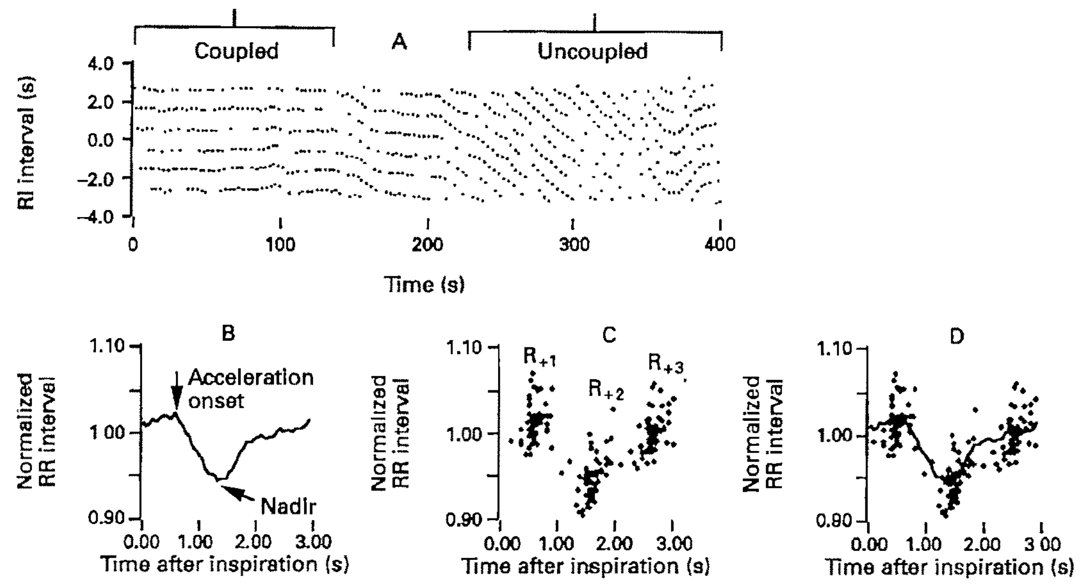

Figure 2 A: Representative example of an RI interval time series showing a segment (0–140 s) of strong cardioventilatory phase coupling during which time heart beats occurred in constant relationship to inspiratory onset, and a weakly coupled segment in which heart beats occurred at all phases of the ventilatory cycle (220–400 s). B: Mean value of the normalized, preceding RR interval (RR interval/mean RR) for time periods after inspiratory onset (RSA curve) was determined from the weakly coupled segment. Acceleration onset and nadir were measured. C: Normalized RR values for intervals derived from the strongly coupled segment show grouping of RR intervals as a result of the timing relationship between R waves and inspiratory onset. D: Superimposition of plots B and C demonstrates that the heart beat grouping R_{+1} has fallen at the acceleration onset of the RSA curve and has therefore been preceded by the longest possible RR interval, and that the R_{+2} grouping has fallen at the RSA nadir and has therefore been preceded by the shortest RR interval for that RSA curve.

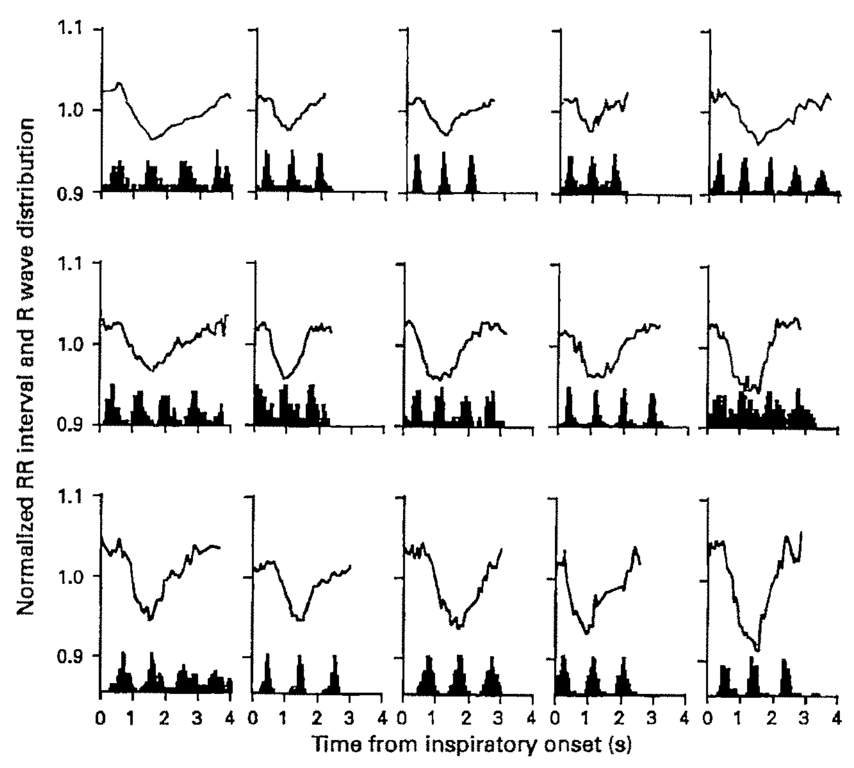

Figure 3 For each subject the figure shows the RSA curve (normalized preceding RR interval *vs* time after inspiration) for weakly coupled segments and histograms of R wave distribution during strong coupling. Note the concordance between the first R wave grouping (R_{+1}) and acceleration onset, and the concordance between the second R wave grouping (R_{+2}) and nadir of the RSA curve.

18–62) yr; nine received an opioid, five morphine, four fentanyl). In the remaining five subjects, the degree of coupling remained constant throughout the recording period and no clear separation between periods of strong and weak or absent coupling were obtained.

From the 15 suitable recordings, during periods of weak or absent coupling, the scattered distribution of heart beats throughout the ventilatory cycle allowed RSA plots to be obtained, all subjects showing the expected heart rate acceleration after inspiratory onset. The nadir of the RSA curve (i.e. the time of an

R wave which has been preceded by the shortest possible RR interval) varied between subjects, with a mean time from inspiratory onset of 1.35 (SD 0.32) s. The onset of acceleration (i.e. the time of an R wave which has been preceded by the longest possible RR interval) occurred at a mean time of 0.43 (0.23) s after inspiratory onset.

Data epochs used for establishing the RSA curve and strongly coupled R wave groupings were not significantly different with regard to mean RR interval (0.896 *vs* 0.893 s; P=0.95, paired t test) or ventilatory frequency (20.2 *vs* 19.7 bpm; P=0.76, paired t test).

RSA plots from strongly coupled segments all showed clustering of heart beats at discrete time intervals after inspiratory onset. Superimposition of these strongly coupled R wave groupings and the previously constructed RSA curves (fig. 2) showed that during strong coupling, the heart beats corresponding to the R_{+1} and R_{+2} groupings generally occurred on, or close to, the acceleration onset and nadir of the RSA curve, respectively. The distribution of heart beats and corresponding RSA plots for all subjects are shown in figure 3. The mean RI_{+2} for strongly coupled beats was not significantly different from the time to RSA nadir (RI_{+2} 1.29 (0.22) s (95% confidence intervals (CI) 1.18–1.40) *vs* nadir 1.35 (0.32) s (95% CI 1.19–1.50); P=0.22, paired t test). Power analysis indicated that there was an 80% probability of a difference of 10% or greater being found statistically significant. Similarly, RI_{+1} was not significantly different from the acceleratory onset of the RSA plot (RI_{+1} 0.418 (0.16) s (95% CI 0.340–0.497) *vs* acceleration onset 0.429 (0.23) s (95% CI 0.314–0.544); P=0.94, paired t test).

Time from inspiratory onset to R_{+1} showed a significant positive correlation with time to the start of acceleration of the RSA curve (r=0.63, $P < 0.01$). Time to nadir and mean RI_{+2} were also positively correlated (r=0.85, P<0.0001). Thus as R wave groupings shifted with changes in heart rate, so also did the reference points on the RSA plot.

Discussion

The observations in this study link the timing of CVC to that of RSA suggesting that, during coupling, heart beats are positioned in such a way that vagal modulation of RSA is maximized. In the absence of CVC, heart beats occur at random positions within the RSA curve and are subjected to varying degrees of vagal modulation. Less inspiratory acceleration of RR interval might be expected if heart beats occur at the sides of the RSA curve. In the presence of CVC however, heart beats were generally subjected to the maximal effects of RSA. $RR_{+1/+2}$ was the shortest possible interval for that RSA curve implying the greatest degree of vagal withdrawal. $RR_{-1/+1}$ was the longest possible interval implying that, during strong coupling, vagal withdrawal at the cardiac sinus pacemaker begins to occur only after the R_{+1} heart beat.

Any putative optimization of RSA by CVC implies a physiological benefit from these processes. Whether the relationship between RSA and phase coupling is simply fortuitous however, or the result of evolutionary design remains open to question. Demonstration of this relationship strengthens the case for their having some physiological significance. A commonly held view with regard to RSA is that it compensates for the haemodynamic effects of varying intrathoracic pressure with ventilation, perhaps matching cardiac output to the variation in venous return or reducing the fluctuations in mean arterial pressure.[6] Evidence for this haemodynamic benefit is poor and an alternative hypothesis has been put forward recently with the demonstration, in dogs, that in contrast with the condition where RSA is absent, artificially induced RSA had no effect on cardiac output, but significantly improved pulmonary oxygenation: reducing the ratio of physiological deadspace to tidal volume, decreasing shunt fraction and increasing oxygen uptake.[7] The mechanism of this effect may be a simple reduction of the time over which blood is replaced within pulmonary capillaries when alveoli are filled with fresh gas, and a lengthening of blood replacement time towards the end of expiration when $\dot{V}/\dot{Q}$ mismatch is more likely and the alveoli are filled with gas of reduced $P\text{A}_{O_2}$ and increased $P\text{A}_{CO_2}$.

Alone, RSA would be unable to achieve synchronization of heart beat timing to ventilation as heart beat timing is determined by the independent sinus pacemaker which is only slowed or accelerated by vagal activity. By triggering inspiration from baroreceptor afferents however, heart beats can be made to occur in exact relationship with the inspiratory period. Thus in the presence of coupling, the shortest possible RR interval and hence pulmonary capillary transit time occurs as the alveoli are filling with fresh gas. The longest RR interval and capillary transit time occur at the end of the ventilatory cycle when the alveoli are filled with "stale" alveolar gas. Although this effect may have little significance for well ventilated areas of the lung, it may become important in those areas where ventilation is low relative to perfusion or in those subjects where FRC approaches closing volume.

If pulmonary gas exchange is improved by RSA and this in turn is optimized by CVC, then this would be consistent with the conditions under which RSA and coupling are known to occur. It is well recognized that sleep, sedation and general anaesthesia, and the accompanying supine posture, may be associated with impaired ventilation, gas exchange and reduced functional residual capacity. Under normal physiological conditions, coupling is best seen during sleep.[3] Sinus arrhythmia is also of greatest amplitude during sleep and in the supine posture because of increased vagal tone.[3 9] It is therefore possible that these mechanisms act to reduce the effects of sleep or supine posture, or both, on disordered gas exchange. It is also perhaps of note that both RSA and phase coupling occur less frequently in REM sleep than in non-REM and this may explain in part why REM sleep is associated with poorer gas exchange than non-REM sleep.

In this study, in order to maximize the accuracy of data collection, we have used data from patients undergoing general anaesthesia. Anaesthesia is plainly a non-physiological state, and the degree of RSA may be altered by the effects of anaesthetic agents and adjuvants.[10] Heart rates of our patients (mean 66 beat min^{-1}) were similar to those occurring during natural sleep[11] and the timing of inspiratory onset, relative to R_{-1}, was the same as that found for awake resting and sleeping subjects who exhibit cardioventilatory coupling.[3] Ventilatory frequencies in our patients (mean 20 bpm) were generally a little higher than those found during sleep (15 bpm[11]) and therefore study of the interaction between RSA and coupling in natural sleep would be warranted.

We have demonstrated a close relationship between RSA vagal modulation and heart beat timing during strong cardioventilatory synchronization, where heart beats and inspiration are in perfect synchrony. However, this pattern of coupling occurs to a variable extent; in some anaesthetized patients it makes up the entire data record whereas in others it is absent. We have described previously at least six patterns of coupling.[8] Again the relevance of this interaction between RSA and CVC may depend on the pattern of coupling seen in sleeping subjects and the degree of RSA "optimization" seen with each pattern.

Respiratory sinus arrhythmia diminishes with advancing age whereas phase coupling persists.[2 3] Although this may simply reflect the robustness of the phase coupling mechanism in contrast with the effect of ageing on vagal tone, the persistence of coupling with age may help to maintain the maximum inspiratory acceleration of heart rate in the face of diminishing RSA magnitude. Alternatively, it is possible that coupling may have physiological benefits independent of any effect on optimizing RSA.

In summary, during anaesthesia, cardioventilatory coupling places heart beats at positions relative to inspiratory onset where they are maximally affected by the vagal modulation of respiratory sinus arrhythmia. This interaction between respiratory and cardiac timing strengthens the argument for their having significant and perhaps common physiological roles. Despite its potential importance, cardioventilatory coupling is not incorporated in current models of respiratory sinus arrhythmia and the present trend towards spectral or frequency domain measurement of RSA only serves to mask the timing relationship between heart beats and ventilation at the expense of obtaining frequency information alone. Disordered cardioventilatory timing relationships may have significant implications for critically ill patients, the provision of IPPV and abnormalities of cardiac rate control.

Cardiovascular effects of 50% nitrous oxide in older adult patients anaesthetized with isoflurane or halothane

M. S. McKinney and J. P. H. Fee

Summary

We have studied the cardiovascular effects of equipotent concentrations of halothane or isoflurane, with or without 50% nitrous oxide in oxygen, in 80 patients, aged 60 yr or more, during 20 min of stable equipotent anaesthesia. Non-invasive measurement techniques were used, with suprasternal Doppler ultrasonography for estimating cardiac output. Both isoflurane and halothane reduced heart rate and systemic arterial pressure. With isoflurane, mean rate decreased from 72 (SD 9.7) to 67 (10.4) beat min^{-1} and with halothane from 76 (10.1) to 65 (9.1) beat min^{-1} ($P<0.05$). Mean diastolic arterial pressure decreased from 81 (11.3) to 58 (17.0) mm Hg with isoflurane and from 86 (14.7) to 70 (13.3) mm Hg with halothane ($P<0.05$). Cardiac index decreased from 3.1 (1.03) to 2.7 (0.71) litre min^{-1} m^{-2} with isoflurane and from 3.1 (0.98) to 2.5 (0.57) litre min^{-1} m^{-2} with halothane ($P<0.05$). Systemic vascular resistance decreased significantly in all groups except those receiving halothane with nitrous oxide. Nitrous oxide resulted in significantly less depression of cardiac index when given with isoflurane than when given with halothane. The mean percentage change in cardiac index during isoflurane anaesthesia without nitrous oxide was 16.7%; with nitrous oxide there was a 0.5% increase. Halothane, in combination with nitrous oxide, resulted in greater depression of cardiac index than isoflurane with nitrous oxide. The mean percentage change with halothane was 20.4% (22.2%); with isoflurane there was a 0.5% (27.1%) increase ($P<0.05$). Hypotension was more pronounced in patients anaesthetized with isoflurane ($n=40$) than those anaesthetized with halothane ($n=40$), irrespective of the presence of nitrous oxide. The mean percentage decrease with isoflurane was 29.7% (21.10%) compared with 16.8% (16.78%) with halothane ($P<0.05$). (*Br. J. Anaesth.* 1998; **80**: 169–173)

Nitrous oxide has been shown to cause both deleterious and beneficial changes in arterial pressure and heart rate when given with halothane.[1–3] Martin and colleagues[4] have shown that it improves myocardial contractility during halothane anaesthesia. Previously published work by our group showed that cardiac output was less well maintained in elderly patients compared with their younger counterparts during isoflurane anaesthesia.[5] We attributed this to reduced cardiovascular sensitivity to sympathetic stimulation.

We report on the cardiovascular effects of nitrous oxide when given with halothane or isoflurane in the elderly.

Patients and methods

After obtaining approval from the University Research Ethics Committee and written, informed consent, we studied 80 ASA I or II patients, aged 60 yr or more, within 20% of their predicted lean body mass. Patients were not included if they were receiving cardioactive medication or had a history of cardiovascular disease, had recently received halothane or had a history of malignant hyperpyrexia. Temazepam 10–20 mg orally was given 1 h before the study commenced.

Patients were allocated randomly to one of four groups ($n=20$ in each) to receive isoflurane or halothane at 1 MAC end-tidal concentration in 100% oxygen (1.05% or 0.65%, respectively) or the same agents in a 50% mixture of nitrous oxide in oxygen at 1 MAC (0.55% or 0.35%, respectively). Cardiac output was measured using a Datascope Accucom cardiac output monitor. This device uses the Doppler principle to measure blood velocity in the ascending aorta. Measurements were obtained in duplicate from the suprasternal notch. Baseline measurements of cardiac output, systemic arterial pressure and heart rate were made after a 10-min period of stabilization in the anaesthetic room. Systemic arterial pressure and heart rate were measured by a Datascope Accutorr and the ECG was monitored throughout the study. All the data were collected before surgery commenced.

Anaesthesia was induced with etomidate 0.3 mg kg^{-1} followed by 1-mg increments for initial maintenance. Atracurium 0.5 mg kg^{-1} was given at the same time to facilitate tracheal intubation with a Portex gas sampling tube, performed 90 s after induction. Two minutes after intubation (time 0) the

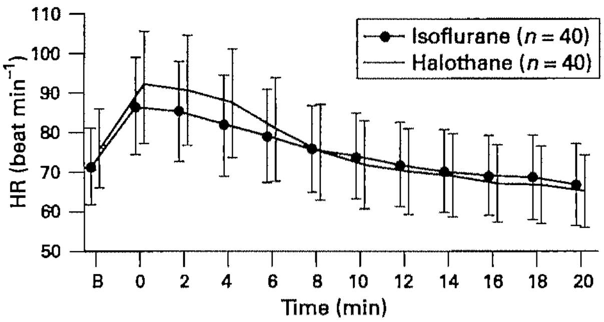

Figure 1 Mean (SD) heart rate (HR) in all subjects receiving isoflurane or halothane.

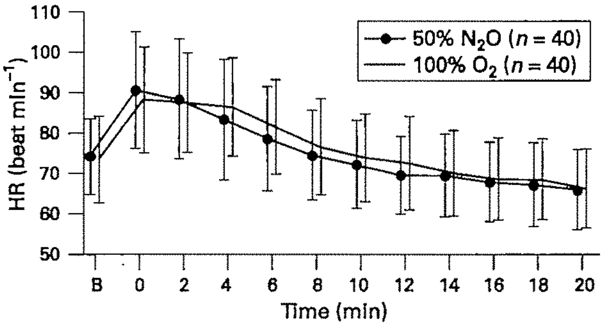

Figure 2 Mean (SD) heart rate (HR) in all subjects receiving either volatile agent and 50% nitrous oxide (N_2O) in oxygen or 100% oxygen (O_2).

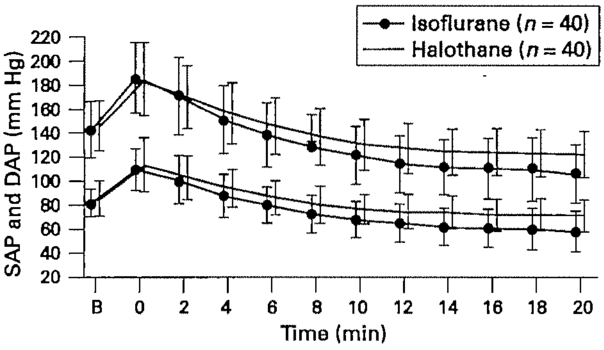

Figure 3 Mean (SD) systolic (SAP) and diastolic (DAP) arterial pressures in patients receiving 1 MAC of isoflurane or halothane.

volatile agent was introduced at an inspired concentration chosen to attain 1 MAC (end-tidal) within 2 min. The lungs were ventilated to an end-tidal carbon dioxide partial pressure of 4.5 kPa. Measurements of arterial pressure, heart rate, cardiac output and volatile agent were made at time 0 and every 2 min for 20 min. During this time the patient remained undisturbed and the inspired volatile agent concentration was adjusted to maintain 1 MAC expired concentration, as measured by a Datex Normac.

Data were collected on-line using a BBC microcomputer which was interfaced with the Accucom and the Normac.[6] The computer collected and stored data on arterial pressure, heart rate and cardiac output, together with other Doppler information (ejection time, signal strength and heart rate). It also sampled intermittently the concentration of volatile agent over a 10-s period from the Normac and calculated peak and trough concentrations of volatile agent. The Normac/computer system was calibrated with a standard gas before each study. Data were stored on diskette for later retrieval. Cardiac index, stroke distance and minute distance were calculated for each measurement using a nomogram-derived estimate for body surface area.

Results were analysed using two- or three-factor repeated measures analysis of variance to give a broad perspective. To improve the power of the factorial design of the study, summary measures were made for each of the measured variables. Two-factor ANOVA was then used to compare the effects of volatile agent or nitrous oxide, or both, using contrast analyses, with the Newman–Keul's test for appropriate individual comparisons. Chi-square and Mann–Whitney *U* tests were applied to non-parametric data. $P<0.05$ was considered statistically significant.

Results

Table 1 shows patient characteristics, ventilation and drug doses for the four study groups.

Over the duration of the study, isoflurane (n=40) had less of an effect on heart rate than halothane (n=40) (fig. 1) and the addition of nitrous oxide did not alter the changes in heart rate (n=40) (fig. 2).

Halothane (n=40) caused a smaller decrease in both systolic and diastolic arterial pressures than isoflurane ($P<0.05$) (fig. 3) but these effects were reduced by the addition of nitrous oxide (n=40) ($P<0.05$) (fig. 4).

Cardiac index decreased significantly over the study in all groups (n=80) (fig. 5) and was affected similarly by the two agents (table 2). The addition of nitrous oxide produced different effects on cardiac index depending on the volatile agent: with isoflurane it was better maintained ($P<0.05$) (n=20) but with halothane the depression was accentuated ($P<0.05$) (n=20) (fig. 6).

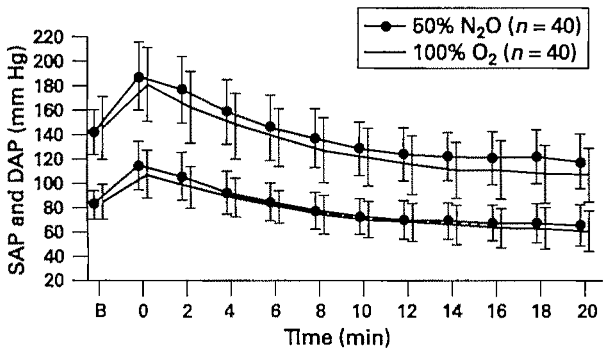

Figure 4 Mean (SD) systolic (SAP) and diastolic (DAP) arterial pressures in patients receiving either volatile agent and 50% nitrous oxide in oxygen or 100% oxygen.

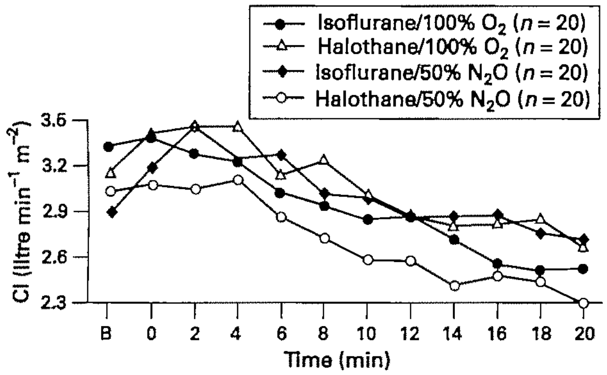

Figure 5 Mean (SD) cardiac index (CI) in all four groups.

Table 2 Mean (SD) cardiac index values at baseline and after 20 min of 1 MAC of anaesthesia. Summary data are presented under each category. For example, in the case of isoflurane, the mean cardiac index is calculated from the pooled isoflurane—nitrous oxide (N_2O) and isoflurane—oxygen (O_2) data

	Baseline	20 min
All isoflurane cases	3.1 (1.03)	2.7 (0.71)
All halothane cases	3.1 (0.98)	2.5 (0.57)
All 50% N_2O—O_2 cases	3.0 (0.80)	2.5 (0.60)
All 100% O_2 cases	3.2 (1.16)	2.7 (0.70)

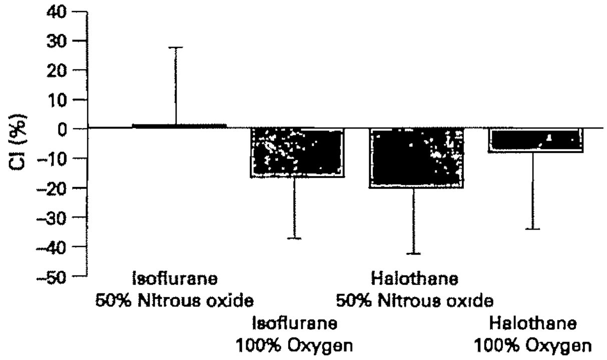

Figure 6 Mean (SD) percentage change in cardiac index (CI) from baseline values in the four groups.

Systemic vascular resistance was reduced to a greater extent by isoflurane than halothane (n=40) (P<0.05) (fig. 7). There was little change when nitrous oxide was added to either agent (n=40) (P> 0.05) (fig. 8).

Discussion

Ventilation to an end-tidal carbon dioxide value of 4.5 kPa was based on previous work[7] which demonstrated that this value resulted in normocapnia in this age group of patients. Indeed, arterial blood samples showed that mean arterial $P\text{CO}_2$ was 4.9 kPa.

Atracurium was chosen because of its minimal effect on the cardiovascular system. Other neuromuscular blocking agents have been associated with vagal reactions and altered pharmacokinetics in the elderly.

Most studies on the cardiovascular effects of nitrous oxide alone would suggest that it exhibits a sympathomimetic action[8 9] and these effects have also been demonstrated when nitrous oxide is used in conjunction with other anaesthetic agents, with an increased systemic vascular resistance being the most consistent finding.[4 10 11]

Reports on the effect of nitrous oxide in combination with volatile anaesthetic agents on heart rate have been inconsistent.[11–13] In the older adult, isoflurane in oxygen was associated with a decrease in heart rate[5] and the addition of nitrous oxide (with equal anaesthetic potency) has now been shown to increase this effect. Halothane in oxygen was also associated with a reduced heart rate but nitrous oxide did not change this effect. These findings, attributed to the limited responsiveness of the aged cardiovascular system to sympathomimetic effects,[14–19] may explain the absence of an increase in heart rate in this study.

It has been demonstrated previously that nitrous oxide reduces the decline in arterial pressure associated with isoflurane[12 20] and halothane[21 22] in healthy young adults, a finding corroborated by these results. The use of 100% oxygen in the control group may itself have contributed to some cardiovascular changes, although oxygen alone has been shown to increase arterial pressure and systemic vascular resistance.[23]

Systemic vascular resistance was increased by the addition of nitrous oxide to halothane but was reduced similarly in both groups receiving isoflurane anaesthesia. As a sole agent or in conjunction with halothane, nitrous oxide has been shown to exert a peripheral vasoconstricting effect in healthy adults and animals.[3 10 11 24] However, these effects were not replicated during isoflurane anaesthesia; indeed Dolan and colleagues[20] indicated that systemic vascular resistance was higher in the absence of nitrous oxide, although they did not compensate for altered anaesthetic potency.

Isoflurane, halothane and nitrous oxide exhibit dose-dependent myocardial depression by interacting with Ca^{2+} effects in the myocyte,[25–27] although the exact mechanisms may differ between halothane and isoflurane.[28–30] Reducing the concentration of the volatile agent by adding a less potent myocardial depressant drug (nitrous oxide)[26] should reduce depression of cardiac function, but we found that this occurred only with isoflurane. Lawson, Frazer and Lynch[27] found that nitrous oxide, in common with halothane, reduced Ca^{2+} release from the sarcoplasmic reticulum of the myocyte but that the effects of isoflurane were of a different character. However, they found that the addition of nitrous oxide to either halothane or isoflurane caused simple additive depression of myocardial function with both agents. There is evidence that uptake of Ca^{2+} by sarcoplasmic reticulum of aged myocytes is deficient[31] and this

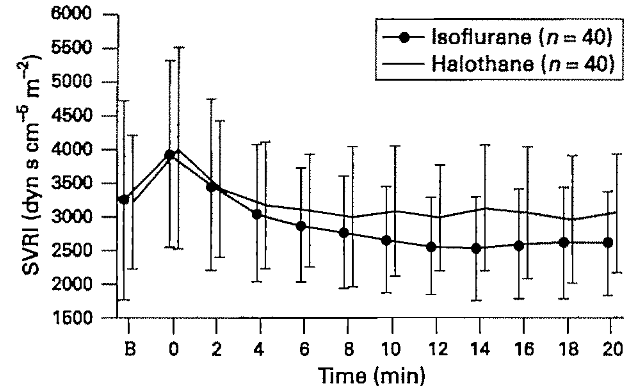

Figure 7 Mean (SD) systemic vascular resistance index (SVRI) in patients receiving 1 MAC of isoflurane or halothane.

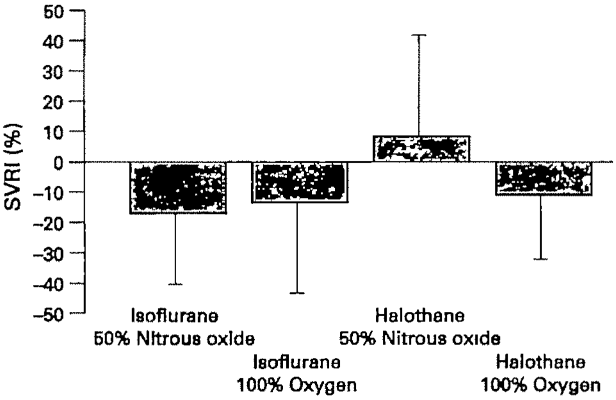

Figure 8 Mean (SD) percentage change in systemic vascular resistance index (SVRI) in the four groups.

would result in a lower Ca^{2+} content of the sarcoplasmic reticulum.[32] Thus the combined effects of halothane and nitrous oxide on release of Ca^{2+} from this organelle may be more potent in the older heart. Certainly, nitrous oxide produced a marked decrease in stroke volume during halothane anaesthesia whereas a significant increase was seen with isoflurane.

Cardiovascular changes are modified in the intact animal by autonomic corrective reflexes. Together with halothane, isoflurane, and the effects of ageing,[33 34] nitrous oxide has been shown to reduce baroreflex function.[3] However, Duke and Trosky[2] suggested that baroreflex depression at equipotent anaesthetic concentrations with halothane was less when nitrous oxide formed part of the technique. Although arterial pressure was still decreased when nitrous oxide was used, the corrective heart rate response was not seen in this study. In fact, there was further slowing of the heart during isoflurane anaesthesia. This may suggest that the baroreflex is reset at a lower level and that the slightly higher arterial pressure in the presence of nitrous oxide results in reflex slowing of the heart.

The presence of nitrous oxide in the anaesthetic gas mixture should result in a faster uptake of volatile agent as a result of the second gas effect.[35 36] This would shorten the onset time of the volatile agent and may be partly the reason for the greater depression when nitrous oxide is added to halothane.

In summary, 1 MAC of isoflurane anaesthesia with 50% nitrous oxide in older adult patients resulted in less depression of systemic arterial pressure and cardiac output than 1 MAC (equipotent) of isoflurane alone; there was, however, greater depression of heart rate. Systemic vascular resistance was unaffected. Nitrous oxide with halothane resulted in a greater decrease in cardiac output, increased systemic vascular resistance and no alteration in heart rate. This suggests that, in terms of cardiovascular responses, nitrous oxide supplementation may be beneficial during isoflurane, and detrimental during halothane anaesthesia in older age groups.

Influence of 0.1 minimum alveolar concentration of sevoflurane, desflurane and isoflurane on dynamic ventilatory response to hypercapnia in humans

M. VAN DEN ELSEN, E. SARTON, L. TEPPEMA, A. BERKENBOSCH AND A. DAHAN

Summary

To assess the effects and site of action of a subanaesthetic concentration of isoflurane, desflurane and sevoflurane (0.1 minimum alveolar concentration (MAC)) on respiratory control, we measured the ventilatory response to square wave changes in PE'_{CO_2} against a background of normoxia. Using the computer steered "end-tidal forcing system", 2 min of steady state ventilation were followed by a step increase in PE'_{CO_2} (1–1.5 kPa). This level was maintained for 8 min, followed by a step decrease to the original value for another 8 min. Each hypercapnic response was separated into a fast, peripheral component and a slow, central component, characterized by a time constant, carbon dioxide sensitivity, time delay and off-set. We studied 25 healthy volunteers; they performed 2–3 studies without and 2–3 studies during inhalation of the anaesthetic agent. Level of sedation was scored using a subjective seven-point scale from 0 (= alert and awake) to 6 (unrousable). In the isoflurane (16 subjects, 33 control, 37 drug studies) and sevoflurane (15 subjects, 40 control, 41 drug studies) studies, peripheral carbon dioxide sensitivity was reduced by approximately 45% and approximately 27% (ANOVA, $P < 0.05$ *vs* control), respectively, without affecting central carbon dioxide sensitivity or apnoeic threshold. In the desflurane study (16 subjects, 36 control, 37 drug studies), no significant effect was observed for any of the variables measured. A significant relation was observed between sedation score and change from control in central carbon dioxide sensitivities in the isoflurane and desflurane studies and in the change in the ratio peripheral carbon dioxide sensitivity over total carbon dioxide sensitivity in the sevoflurane studies. At the highest level of sedation observed (score 3–arousal state comparable with "light sleep"–in three subjects) these latter variables differed significantly from those in the other observed sedation levels (scores 1 and 2–a state of drowsiness). We conclude that 0.1 MAC of isoflurane and sevoflurane depressed the peripheral chemoreflex loop, without affecting the central chemoreflex loop. Desflurane at the same MAC showed no effect on peripheral and central carbon dioxide sensitivity. When the level of sedation was considered, our data suggested that at levels of sedation comparable with sleep, a depressive effect of all three anaesthetics was observed on the central chemoreflex loop. (*Br. J. Anaesth.* 1998; **80**: 174–182)

Keywords: anaesthetics volatile, desflurane; anaesthetics volatile, isoflurane; anaesthetics volatile, sevoflurane; ventilation, hypoxic response; hypoxaemia

Sevoflurane and desflurane are two new inhalation anaesthetics. Earlier studies from our laboratory showed that in healthy volunteers, desflurane at 0.1 minimal alveolar concentration (MAC) did not affect the ventilatory response to normocapnic hypoxia but decreased significantly the response to asphyxia (hypercapnic hypoxia).[1] Sevoflurane at 0.1 MAC caused a reduction in the hypoxic response by approximately 30%.[2] Similar MAC fractions of isoflurane and halothane produced a more marked decrease in the hypoxic response (50% or more) in an equivalent group of healthy subjects.[3 4] Results of studies on the influence of 0.1 MAC of halothane and isoflurane on the ventilatory response to inhaled carbon dioxide were in agreement with the results of the hypoxic studies.[3 4] Moreover, carbon dioxide studies revealed a selective depressant effect of 0.1 MAC of halothane and isoflurane on the peripheral chemoreflex loop. None of the anaesthetics tested showed a significant effect on carbon dioxide sensitivity of the central chemoreceptors.

In order to study the influence of 0.1 MAC of desflurane and sevoflurane on the carbon dioxide related output of the peripheral and central chemoreflex loops, we determined ventilatory responses to square-wave changes in end-tidal carbon dioxide tension (PE'_{CO_2}) against a background of normoxia. The ventilatory responses, measured on a breath-by-breath basis were then partitioned into a fast, peripheral and a slow, central component, using a two-compartment model.[5 6]

Subjects and methods

We studied 25 healthy volunteers (12 women, 13 men, aged 22–37 yr), with no history of smoking, drug or alcohol abuse. The study was approved by the Leiden

University Committee on Medical Ethics and informed consent was obtained before the study. Subjects were unfamiliar with respiratory physiology but received information on the nature of the study. All had participated in several studies on respiratory physiology in our laboratory. Therefore, a test session was not required. Subjects were asked to refrain from stimulants and depressants for at least 12 h before the study.

During the study, subjects were in a semi-recumbent position (135° between lower extremities and thorax). Soft music was played and subjects were instructed to keep their eyes closed throughout the studies. An oronasal mask (Vital Signs, USA) was fitted before the experiment started. Airway gas flow was measured with a pneumotachograph (Fleisch, Switzerland) connected to a differential pressure transducer (model 270, Hewlett Packard, USA) and integrated electronically to yield a volume signal. This signal was calibrated with a motor-driven piston pump. The pneumotachograph was connected to a T-piece. One arm of the T-piece received a gas mixture with a flow of 50 litre min^{-1} from a gas mixing system that consisted of three mass flow controllers (type F201, Bronkhorst High Tec, The Netherlands) with which the flow of oxygen, carbon dioxide and nitrogen could be set individually at a desired level. A PDP 11/23 microcomputer (Digital Equipment Corporation, Maynard, USA) provided control signals to the mass flow controllers, so that the composition of the inspiratory gas mixture could be adjusted to force the end-tidal carbon dioxide and oxygen partial pressures to follow a specific pattern in time. When appropriate, part of the nitrogen (5 litre min^{-1}) was bypassed through the isoflurane, sevoflurane or desflurane vaporizer. During the initial part of the study, the vaporizer was kept in the "off" position. Inspiratory and expiratory concentrations of oxygen and carbon dioxide were measured with a gas monitor (Datex Multicap, Finland) by paramagnetic and infrared analysis, respectively. The gas monitor was calibrated with gas mixtures of known concentrations. The concentrations of isoflurane, desflurane and sevoflurane were measured at the mouth with a Datex Capnomac Ultima. Inspiratory minute ventilation ($\dot{V}\mathrm{I}$), and end-tidal concentrations of oxygen and carbon dioxide ($P\mathrm{E}'_{\mathrm{O_2}}$ and $P\mathrm{E}'_{\mathrm{CO_2}}$, respectively) were calculated and stored on a breath-by-breath basis.

STUDY DESIGN

We used a computer steered "end-tidal forcing system" to obtain stepwise increases and decreases in $P\mathrm{E}'_{\mathrm{CO_2}}$ while maintaining $P\mathrm{E}'_{\mathrm{O_2}}$ at a normoxic level ($P\mathrm{E}'_{\mathrm{O_2}}$ =14.5 kPa). After arrival in the laboratory, subjects rested for at least 30 min. Each hypercapnic study started with a period of "steady-state" ventilation of approximately 10 min during which $P\mathrm{E}'_{\mathrm{CO_2}}$ was held at 0.2–0.3 kPa above resting. The reason for this increase was to allow the end-tidal forcing system adequately to control $P\mathrm{E}'_{\mathrm{CO_2}}$ by manipulation of the inspired $P\mathrm{CO_2}$. Subsequently, $P\mathrm{E}'_{\mathrm{CO_2}}$ was increased by 1–1.5 kPa within 3–5 breaths, maintained constant for approximately 8 min and then returned, in a single step, to the original value and maintained for another 8 min.

Each subject performed 2–3 studies without and 2–3 studies during inhalation of the anaesthetic agent. Control studies always preceded drug studies. Before we started a drug experiment we allowed an equilibration period of 20 min for isoflurane and 15 min for sevoflurane and desflurane after the appropriate end-tidal concentration had been reached. The target end-tidal concentrations used were 0.125%, 0.72% and 0.22% (approximately 0.1 MAC) for isoflurane, desflurane and sevoflurane, respectively. Throughout the studies, end-tidal concentrations were maintained at target levels by manipulation of the vaporizer by one of the investigators (M. vd E., E. S. or A. D.).

Sixteen subjects participated in the isoflurane and desflurane studies and 15 in the sevoflurane study. Seven subjects participated in all three studies. A single anaesthetic was tested on a particular morning session. Sessions were at least 2 weeks apart. The results of the isoflurane studies of eight subjects have been published previously.[4]

DATA ANALYSIS

The steady-state relation of $\dot{V}\mathrm{I}$ TO $P\mathrm{E}'_{\mathrm{CO_2}}$ at constant $P\mathrm{E}'_{\mathrm{O_2}}$ in humans is described by:

$$\dot{V}\mathrm{I} = (G_{\mathrm{P}} + G_{\mathrm{C}})\ (P\mathrm{E}'_{\mathrm{CO_2}} - B) \qquad (1)$$

where G_{P} = carbon dioxide sensitivity of the peripheral chemoreflex loop; G_{C} = carbon dioxide sensitivity of the central chemoreflex loop; and B = apnoeic threshold or extrapolated $P\mathrm{E}'_{\mathrm{CO_2}}$ of the steady-state ventilatory response to carbon dioxide at zero $\dot{V}\mathrm{I}$. The sum of G_{P} and G_{C} is total carbon dioxide sensitivity (G_{TOT}).

For analysis of the dynamic response of ventilation, we used a two-compartment model[5 6]:

$$\tau_{\mathrm{P}}\ \mathrm{d}/\mathrm{d}t\ \dot{V}_{\mathrm{P}}\ (t) = G_{\mathrm{P}}\ (P\mathrm{E}'_{\mathrm{CO_2}}\ (t - D_{\mathrm{P}}) - B) - \dot{V}_{\mathrm{P}}\ (t) \qquad (2)$$

$$\tau_{\mathrm{C}}\ \mathrm{d}/\mathrm{d}t\ \dot{V}_{\mathrm{C}}\ (t) = G_{\mathrm{C}}\ (P\mathrm{E}'_{\mathrm{CO_2}}\ (t - D_{\mathrm{C}}) - B) - \dot{V}_{\mathrm{C}}\ (t) \qquad (3)$$

where τ_{P} and τ_{C} = time constants of the peripheral and central chemoreflex loops, respectively; $\dot{V}_{\mathrm{P}}\ (t)$ and $\dot{V}_{\mathrm{C}}\ (t)$ = outputs of the peripheral and central chemoreflex loops, respectively; $P\mathrm{E}'_{\mathrm{CO_2}}\ (t - D_{\mathrm{P}})$ = stimulus to peripheral chemoreflex loop delayed by the peripheral transport delay time (D_{P}); and $P\mathrm{E}'_{\mathrm{CO_2}}\ (t - D_{\mathrm{C}})$ = stimulus of the central chemoreflex loop delayed by the central transport delay time (D_{C}). The time delay represents the transit time for the $P\mathrm{E}'_{\mathrm{CO_2}}$ stimulus to reach the chemoreceptors.

To model τ_{C} of the ventilatory on-transient (τ_{ON}) to be different from that of the off-transient (τ_{OFF}), τ_{C} is written as:

$$\tau_{\mathrm{C}} = \tau_{\mathrm{ON}}\ x + (1 - x)\ \tau_{\mathrm{OFF}} \qquad (4)$$

where $x = 1$ when $P\mathrm{E}'_{\mathrm{CO_2}}$ is high and $x = 0$ when $P\mathrm{E}'_{\mathrm{CO_2}}$ is low.

In most experiments a small drift in ventilation was present. We therefore included a drift term (Ct) in our model. The total ventilatory response $\dot{V}\mathrm{I}(t)$ is made up of the contributions of the central and peripheral chemoreflex loops and Ct:

$$\dot{V}\mathrm{I}(t) = \dot{V}_{\mathrm{P}}(t) + \dot{V}_{\mathrm{C}}(t) + Ct \qquad (5)$$

The parameters of the model were estimated by fitting the model to the breath-by-breath data with a least-squares method. To obtain optimal time delays a "grid search" was applied. All combinations of D_{P} and D_{C}, with increments of 1 s and with $D_{\mathrm{P}} \leqslant D_{\mathrm{C}}$ were tried until a minimum in the residual sum of squares was found. The minimum time delay was chosen arbitrarily to be 1 s, and τ_{P} was constrained to be at least 0.3 s.

Table 1 Leiden observer's assessment of alertness/sedation (LOAA/S) scale

0 = Normal alertness, eyes closed and opened on command
1 = Drowsy with open eyes, closed and opened on demand
2 = Drowsy with closed eyes, opened in response to a light auditory stimulus
3 = Eyes closed, opened in response to rubbing the shoulder or a loud auditory stimulus
4 = Closed eyes, eyes opened only briefly in response to touching the subject
5 = Closed eyes, unrousable by touching the subject, aroused by a painful stimulus
6 = Unrousable by a painful stimulus

SCORING FOR SEDATION AND EXCLUSION CRITERIA

At the start and end of each hypercapnic study, we recorded the central nervous system arousal state by a subjective six-point observer's assessment of alertness/sedation (LOAA/S) scale (table 1). Data were discarded when the LOAA/S score was not 0 in the control studies, irregular breathing, coughing or an apparent change in the arousal state (for example as observed by restlessness) occurred in any of the studies.

STATISTICAL ANALYSIS

For each volatile agent, we determined the significance of differences between the control and drug studies by two-way analysis of variance (ANOVA) on parameters G_P, G_C, G_P/G_{TOT} (ratio) and B using a fixed model. To obtain information on the relationship between sedation score and the difference between drug and control parameters (Δ) we performed a linear regression analysis of ΔG_P, ΔG_C and $\Delta G_P/G_{TOT}$ (Δratio) on sedation score. Further, we determined for each anaesthetic the significance of differences between sedation scores by ANOVA on ΔG_P, ΔG_C and Δratio with *post hoc* multiple comparisons using Newman–Keuls test. Probability levels <0.05 were considered significant. All values are mean (SD), unless otherwise stated.

Results

All subjects completed the study without side effects. A total of 235 ventilation–$P\text{E}'_{CO_2}$ responses were obtained. Eleven studies were discarded because of irregular breathing (four control and seven drug studies, of which isoflurane two, desflurane two and sevoflurane three).

ISOFLURANE STUDIES

Thirty-three control and 37 isoflurane studies were included in the analysis. End-tidal isoflurane concentrations were 0.13 (0.04)% in the drug studies. The LOAA/S scores were 0 in the control studies for all subjects. In the isoflurane studies, scores were 1 in six, 2 in seven and 3 in three subjects. Isoflurane at 0.1 MAC caused peripheral carbon dioxide sensitivity to decrease by 45% ($P = 0.003$), without affecting central carbon dioxide sensitivity or apnoeic threshold (table 2). These changes caused the ratio of peripheral carbon dioxide sensitivity to total carbon dioxide sensitivity ($G_P/(G_P + G_C)$) to decrease by 35% (P=0.01).

SEVOFLURANE STUDIES

Forty control and 41 sevoflurane studies were included in the analysis. End-tidal sevoflurane concentrations were 0.22 (0.04)% in the drug studies. The LOAA/S scores were 0 in the control studies for all subjects. In the sevoflurane studies, scores were 1 in six, 2 in six and 3 in three subjects. During sevoflurane inhalation, peripheral carbon dioxide sensitivity decreased by 27% (P=0.02). Central carbon dioxide sensitivity, ratio and apnoeic threshold were not affected by 0.1 MAC of sevoflurane. The typical fits to the data of two studies of one subject are shown in figure 1.

DESFLURANE STUDIES

Thirty-six control and 37 desflurane studies were included in the analysis. End-tidal desflurane concentrations were 0.70 (0.04)% in the drug studies. The LOAA/S scores were 0 in the control studies for all subjects. In the desflurane studies, scores were 1 in six, 2 in seven and 3 in three subjects. The model fits of a control and desflurane experiment of a subject are shown in figure 1. They indicate no effect on the peripheral or central chemoreflex loop. None of the estimated parameters differed significantly between control and desflurane studies (table 2).

In figure 2, scatter diagrams for G_P, G_C and ratio are given for all three anaesthetics.

INFLUENCE OF LEVEL OF SEDATION

Regression analysis revealed a significant relation between LOAA/S score and the difference in central carbon dioxide sensitivity between drug and control (ΔG_C) in the isoflurane and desflurane studies. The

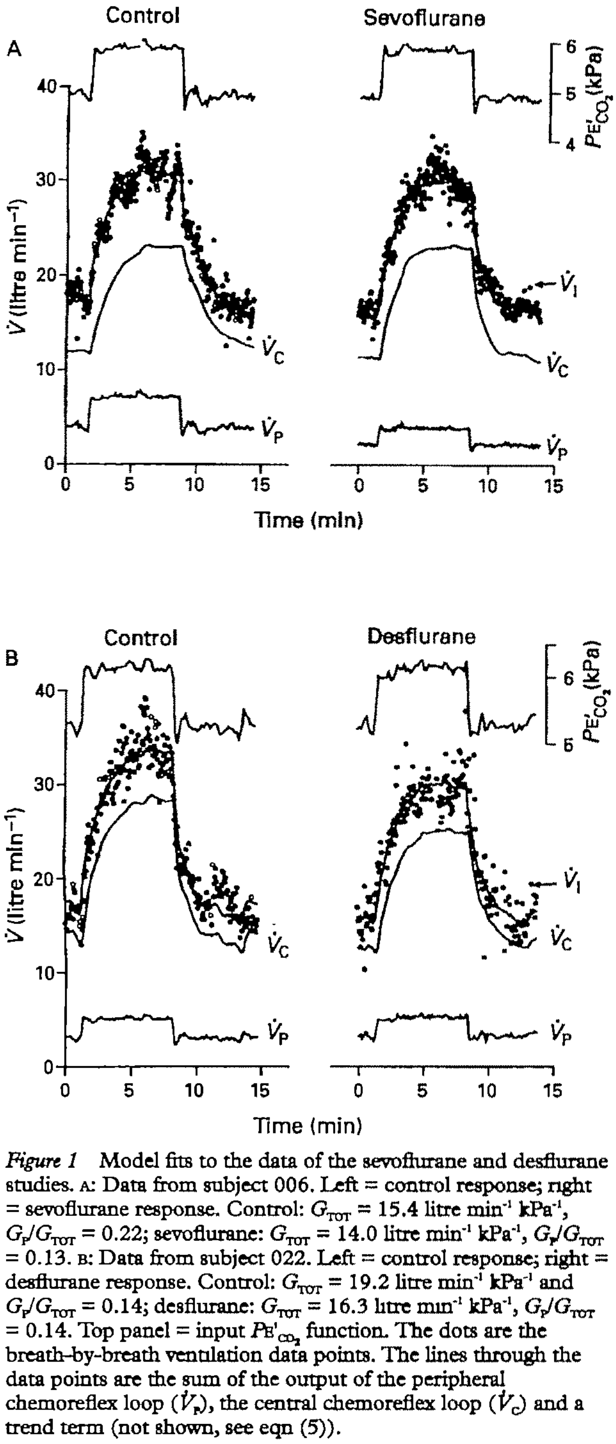

Figure 1 Model fits to the data of the sevoflurane and desflurane studies. A: Data from subject 006. Left = control response; right = sevoflurane response. Control: G_{TOT} = 15.4 litre min^{-1} kPa^{-1}, G_P/G_{TOT} = 0.22; sevoflurane: G_{TOT} = 14.0 litre min^{-1} kPa^{-1}, G_P/G_{TOT} = 0.13. B: Data from subject 022. Left = control response; right = desflurane response. Control: G_{TOT} = 19.2 litre min^{-1} kPa^{-1} and G_P/G_{TOT} = 0.14; desflurane: G_{TOT} = 16.3 litre min^{-1} kPa^{-1}, G_P/G_{TOT} = 0.14. Top panel = input $P\text{E}'_{CO_2}$ function. The dots are the breath-by-breath ventilation data points. The lines through the data points are the sum of the output of the peripheral chemoreflex loop ($\dot{V}_P$), the central chemoreflex loop ($\dot{V}_C$) and a trend term (not shown, see eqn (5)).

value of ΔG_C was smallest in the group with LOAA/S score 3 ($P < 0.05$; see figure 3). In the sevoflurane studies, we observed a significant relation between Δratio and LOAA/S score with Δratio greatest in the group with LOAA/S score 3 ($P < 0.05$; see figure 3). It is of interest to note that subjects with an LOAA/S score of 3 were three females that had participated in all three anaesthetic studies. Their LOAA/S scores were similar in the anaesthetic studies. Exclusion of their data from the analysis would not have affected the conclusion drawn from this study considerably (see fig. 4).

Discussion

Knill and colleagues were the first to study the effects of low concentrations of inhalation anaesthetics on the regulation of breathing in humans.[7–10] In the late 1970s and early 1980s, they tested the effects of halothane, enflurane and isoflurane using several imposed chemical stimuli. Their studies led to the, still generally accepted, conclusion that inhalation anaesthetics selectively impair all responses mediated by the peripheral chemoreceptors at subanaesthetic concentrations (0.05–0.1 MAC).

In order to study the different components of the ventilatory control system, Knill and colleagues used several tests. Using a carbon dioxide rebreathing technique to study the "central" ventilatory response to inhaled carbon dioxide, they observed no depression with 0.1 MAC halothane and isoflurane but approximately 25% depression with 0.1 MAC of enflurane.[7–9] To selectively study the peripheral chemoreflex loop they determined the ventilatory response to a gradual decrease in $P\text{E}'_{O_2}$ over 8–10 min (a so-called "ramp hypoxic step") and to moderate isocapnic metabolic acidosis.[7–10] Hypoxic studies showed a 60% reduction in the ventilatory response with all three anaesthetics at 0.1 MAC; the response to metabolic acidosis was reduced by 60% with 0.1 MAC of halothane. These studies indicated that at least halothane and isoflurane, at 0.1 MAC, affect ventilatory control selectively via an effect on the peripheral chemoreflex loop without an effect on the central chemoreflex loop or pathways common to both loops.

Some of the techniques used by Knill and colleagues have recently come under criticism. The carbon dioxide rebreathing technique, although simple in use, leads to results that are often difficult to interpret, as factors other than those under study determine outcome (such as initial concentration of carbon dioxide in the bag and arterial or end-tidal $P\text{CO}_2$; see Dahan and colleagues[11] and Berkenbosch and colleagues[12] for an analysis of the rebreathing technique). In this respect it is interesting that the results from rebreathing tests in the studies of Knill and colleagues were not uniform for all three anaesthetics. Temp, Henson and Ward demonstrated that the ramp hypoxic test does not allow adequate time for full expression of the hypoxic response from the peripheral chemoreceptors.[13] Tests that allow a more rapid decrease in $P\text{E}'_{O_2}$ (step hypoxic test) are better suited for this purpose and, furthermore, enable the description of the depressant effects of hypoxia.

Despite the important results of the studies of Knill's group it took his personal request and approximately 20 yr before researchers from five independent laboratories investigated the influences of volatile agents on the ventilatory response to imposed chemical stimuli in humans.[14] The availability of hypoxic and hypercapnic tests that give results with less problems in interpretation (compared with the carbon dioxide rebreathing test and the ramp hypoxic test) is probably one of the main reasons. In table 3, data of hypoxic studies from the recent literature are summarized. The results of three institutions indicate an appreciable depressant effect of halothane, enflurane, isoflurane and sevoflurane on the acute hypoxic response to an isocapnic step decrease in $P\text{E}'_{O_2}$.[2–4 15–21] With respect to isoflurane, the results from UCLA and the Karolinska Institute indicate little or only a modest effect on the hypoxic response.[13 22–24 26] To explain these differences we have to take into account the significant differences in the

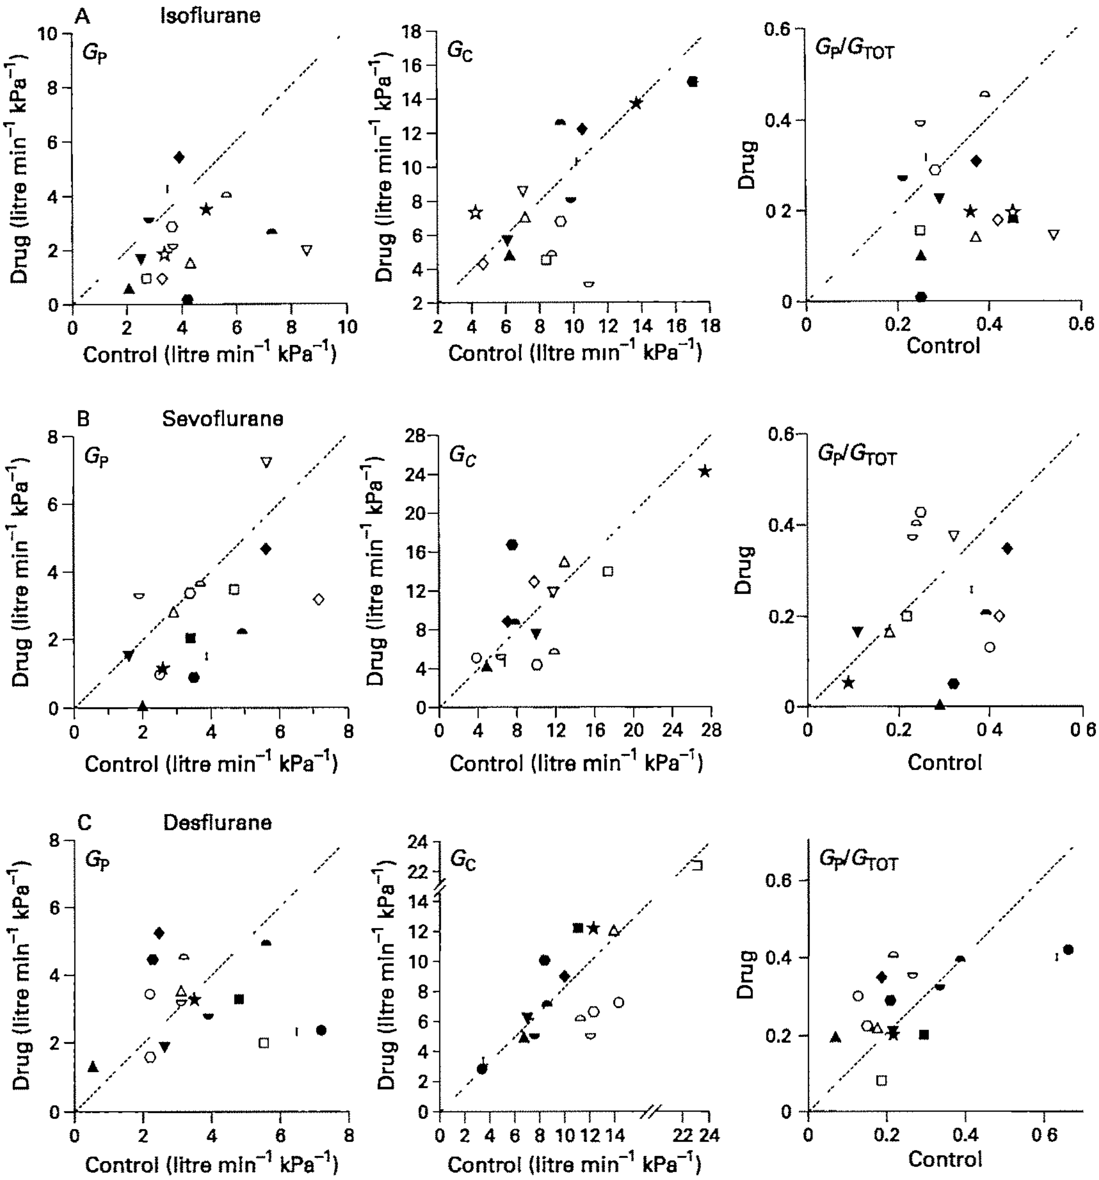

Figure 2 Scatter diagrams of the mean ventilatory carbon dioxide sensitivities of the peripheral (G_P) and central (G_C) chemoreflex loops and the ratio G_P/G_{TOT} ($G_{TOT} = G_P + G_C$). A: Isoflurane study. Each subject has similar symbols in the three diagrams. B = Sevoflurane study; C = desflurane study.

design of the studies. For example, in contrast with the hypoxic studies from the Karolinska Institute and Edinburgh,[16,20,22–25] all those performed in Oxford, UCLA and Leiden had an increased baseline $P\text{E}'_{CO_2}$ of 0.1–0.3 kPa.[3,4,13,15,17–19,21,26] Some of the hypoxic studies from the Karolinska Institute and Edinburgh were not performed under isocapnic conditions or allowed differences in $P\text{E}'_{CO_2}$ between control and drug studies.[16,22–25] One study from Oxford and both from UCLA had an approach to prevent subjects from falling "asleep".[13,18,26] However, we believe that these differences only partly explain the discrepancies in study outcomes.

In comparison with hypoxic studies, studies that investigate the influence of anaesthetics on the ventilatory response to inhaled carbon dioxide are scarce. Previously, we compared the effects of 0.1 MAC of halothane and isoflurane, and observed a 20–25% reduction in steady-state normoxic ventilatory carbon dioxide sensitivity.[3,4] Analysis of the dynamic ventilatory response with the same two-compartment model used in this study revealed that this could be attributed to an effect within the peripheral chemoreflex loop (G_P reduced by approximately 50%) These results are in agreement with those of the hypoxic studies obtained from three of the five institutions (table 3). In contrast, a hypercapnic study from the Karolinska Institute showed no effect of 0.2% end-tidal isoflurane on carbon dioxide sensitivity (anaesthetic response = 0.96 of control response (ns)).[24]

EQUI-MAC-FRACTION DATA

In this study, isoflurane and sevoflurane at 0.1 MAC significantly reduced peripheral carbon dioxide sensitivity without affecting central carbon dioxide sensitivity and the apnoeic threshold. This indicates a selective depressant effect of both anaesthetics on the peripheral chemoreflex loop. These results are in agreement with our hypoxic studies in which we observed a reduction in the acute hypoxic ventilatory response by approximately the same magnitude at 0.1 MAC.[2,4] Desflurane did not influence the ventilatory response to carbon dioxide significantly. With respect to G_P, a decrease was observed in nine

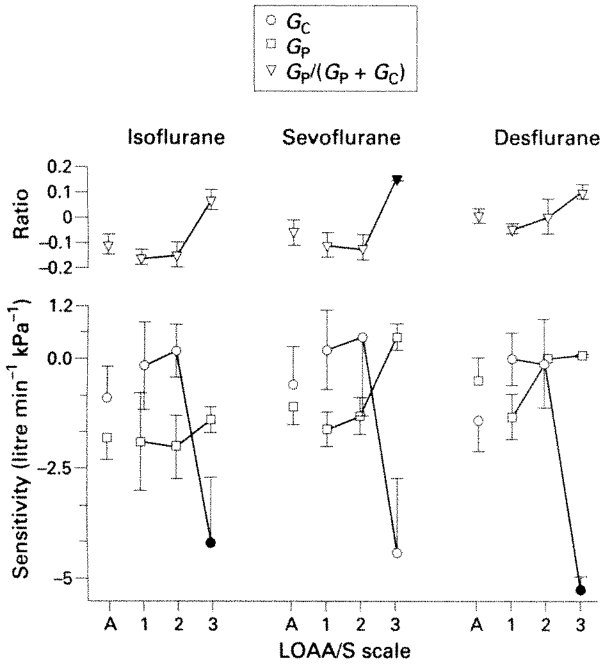

Figure 3 Influence of Leiden observer's assessment of alertness/sedation (LOAA/S) scale on the change from control (Δ) in central carbon dioxide sensitivity (G_C), peripheral carbon dioxide sensitivity (G_P) and ratio ($G_P/(G_P + G_C)$). Regression analysis revealed a significant relation between ΔG_C and LOAA/S in the isoflurane and desflurane studies, and between Δratio and LOAA/S in the sevoflurane studies. The closed data points denote LOAA/S scores significantly different from other scores ($P < 0.05$, ANOVA). A = All scores combined. Values are mean (SEM).

of 16 subjects (there was a trend towards a reduction by approximately 15%). In a previous study we were unable to demonstrate an effect of 0.1 MAC of desflurane on the hypoxic response at normocapnia.[1] However, in that study the ventilatory response to asphyxia was reduced by approximately 30%. This indicates that the peripheral chemoreflex loop does not remain completely unaffected by 0.1 MAC of desflurane. A type II error, therefore, may not be excluded in our current study. The reason for the difference between desflurane and the other two anaesthetics remains unclear. At higher concentrations, desflurane is known to increase sympathetic outflow and irritate the airways.[27 28] We did not observe any signs related to airway irritation or sympathetic activation (for example coughing, breath-holding, sneezing or tachycardia). However, subclinical activation of the sympathetic system and systemic release of catecholamines during hypercapnia and hypoxia may be a possible explanation for the absence of depression of the normoxic ventilatory response to carbon dioxide. It is of interest to note that nitrous oxide, another sympathomimetic agent, at 0.2 MAC influences the ventilatory responses to hypoxia and hypercapnia in a manner similar to desflurane.[29]

At this point, we have to keep in mind that when considering the LOAA/S scores as a measure of the CNS arousal state of individual subjects (equi-sedative data) the above stated conclusions (drawn from equi-MAC-fraction data) need some modification (see below).

SITE OF ACTION

Isoflurane and sevoflurane affected the ventilatory response to carbon dioxide through an exclusive action on parts of the peripheral chemoreflex loop (these are: peripheral chemoreceptors, sinus nerve and sites in the CNS related to the processing of peripheral input). In a previous study we performed the "wash-in" of isoflurane during steady-state isocapnic–hypoxia-driven ventilation.[4] Eighty per cent of the reduction in ventilation occurred within

the first 30 s of isoflurane wash-in. This suggests a selective depressant effect at the site of the peripheral chemoreceptors. However, at 30 s of wash-in some isoflurane may have reached the central nervous system. An additional effect on parts of the peripheral chemoreflex loop such as the sinus nerve or sites within the CNS may therefore not be excluded. Our study indicates that an effect at sites common to the peripheral and central chemoreflex loops is unlikely (i.e. integrating centres, motoneurones, intercostal nerves, phrenic nerves, diaphragm and intercostal muscles, lung, airways) as G_C remained unaffected (at least at LOAA/S levels 1 and 2, see below). When considering a possible action of low-dose isoflurane and sevoflurane at sites *within* the CNS, we speculate that different receptors or neurotransmitters, or both, may be involved in the central processing of afferent input from the peripheral and central chemoreceptors, resulting in marked differences in their resistance to low-dose anaesthetic agents.

INFLUENCE OF LEVEL OF SEDATION

We used a subjective sedation score to assess the level of central nervous system arousal (table 1). Comparison of this score with more objective measures of sedation (for example, the bispectral index of the EEG) indicated the usefulness of our scoring method.[2 30 31] However, we are aware that discrimination between scores is sometimes difficult (especially between scores 1 and 2), and therefore conclusions drawn from these data should be made with caution. We observed a significant relation between LOAA/S score and ΔG_C in the isoflurane and desflurane studies and Δratio in the sevoflurane studies. Further analysis revealed that ΔG_C and Δratio were significantly different in subjects with LOAA/S score 3 compared with those with scores 1 and 2 in the isoflurane and desflurane studies and sevoflurane studies, respectively (fig. 3). In other words, the three subjects with LOAA/S score 3 showed greater depression of G_C compared with G_P. Although we used equipotent concentrations in terms of MAC, these three subjects, all female, had a deeper level of sedation. Inter-individual differences in pharmacodynamics and possibly also differences between the sexes are the most likely explanation for the deeper level of sedation. Our small sample *suggests* that sedation by anaesthetics to levels sufficient to block the perception of or reaction to a light auditory stimulus (that is LOAA/S score > 2, an arousal state comparable with light sleep[2]) results in depression of the hypercapnic ventilatory response at sites within the central chemoreflex loop additional to sites within the peripheral chemoreflex loop. We stress the importance of stating the level of sedation of individual subjects when reporting data on ventilatory control and agents that affect the arousal state, because conclusions drawn from data at equi-MAC-fractions may differ significantly from those drawn at equi-sedative levels.

In summary, 0.1 MAC of isoflurane and sevoflurane, causing a CNS arousal state such that our subjects remained able to respond to a light auditory stimuli, affected the ventilatory control system via an exclusive effect on the peripheral chemoreflex loop. These observations are an extension of earlier findings of Knill and colleagues on isoflurane and halothane. At these concentrations and sedation levels, desflurane seemed exempt from an effect on ventilatory control. Our study suggests that at deeper levels of sedation, all three anaesthetics affected ventilatory control at sites within the central chemoreflex loop. Further studies are needed to investigate the influence of sedation of volatile anaesthetics, as opposed to the MAC of anaesthetics, on ventilatory control.

Urinary excretion as an input variable in volume kinetic analysis of Ringer's solution

R. G. HAHN AND D. DROBIN

Summary

The disposition of fluid given by i.v. infusion can be studied by fitting one-volume and two-volume kinetic models to the fractioned dilution of blood haemoglobin and serum albumin concentrations over time. However, the two-volume model is sometimes associated with a high standard error in estimating the size of the secondary (peripheral) body fluid space, V_2. To examine if a fixed elimination rate constant (k_r) determined by urinary excretion can be used to make the model more stable, we infused Ringer's acetate 25 ml kg^{-1} over 30 min in 15 male volunteers (mean age 35 yr). A fixed k_r increased the total residual error when curve-fitting was applied according to the one-volume model. The two-volume model was improved when there was a strong within-patient covariance between k_r and V_2 ($r^2 \leq -0.98$). The size of V_2 was 10 litre when the fixed and model-generated values of k_r agreed fully. (*Br. J. Anaesth.* 1998; **80**: 183–188)

Keywords: model, pharmacokinetic; model, mathematical; fluid therapy; fluids, i.v.

Volume kinetics is a model for studying how the body handles fluid given by i.v. infusion.[1 2] Dilution of the plasma volume after i.v. infusion can be analysed and simulated over time in a manner similar to drug concentrations in pharmacokinetics.[3 4] The results are sensitive to analytical errors, however, and the choice of mathematical approach is relevant to the stability of the variable estimates.

The key problem is to estimate the size of the secondary (peripheral) fluid space, V_2, which can be overestimated owing to analytical errors in the assay used to quantify dilution of the primary (central) fluid space, V_1.[1] The precision of the estimate is also relatively poor.[3] Occasionally, it is difficult for the model to distinguish between elimination of fluid and distribution of fluid to V_2, which results in a low elimination rate constant (k_r) and an unrealistically large V_2. When this occurs, strong within-patient parameter covariances ($r^2 \leq -0.98$) indicate that k_r and V_2 behave as a single parameter. In these situations, the two-volume fluid space model has been considered invalid,[3] although it might be apparent from the dilution–time curve that the disposition of fluid occurs according to the two-volume model.

The purpose of this study was to evaluate if measured urinary excretion could be used as an input variable to make the volume kinetic model more stable, particularly with respect to V_2. The rationale for our attempt is that nearly all fluid indicated by k_r to be eliminated from the expanded fluid space can be collected as urine.[2] This allows the model to operate with k_r being set to a fixed value which is determined by urinary excretion. The result might be of practical value when using volume kinetic models. The models are also of theoretical interest for our understanding of body fluid volumes and kinetic constants involved in the disposition of crystalloid fluid.

Subjects and methods

After obtaining approved from the local Ethics Committee and informed consent, we studied 15 healthy men, aged 24–42 (mean 35) yr with a body weight of 65–100 (mean 77) kg.

After an overnight fast, volunteers rested comfortably on a bed, and at least 20 min of equilibration were allowed before the experiments were started between 08:00 and 09:00. A cannula was placed in the cubital vein of each arm for blood sampling and infusing fluid, respectively. Volunteers were given an i.v. fluid load consisting of Ringer's acetate solution 25 ml kg^{-1} (Pharmacia, Uppsala, Sweden) over 30 min via an infusion pump (Flo-Gard 6201, Baxter Healthcare, Deerfield, IL, USA). The ionic content of Ringer's solution was (mmol litre^{-1}): Na^+ 130, K^+ 4, Ca^{2+} 2, Mg^{2+} 1, Cl^- 110 and acetate 30. Monitoring of patients included arterial pressure measurements, pulse oximetry and electrocardiography (HP 56S, Hewlett Packard Co., MA, USA). Volunteers were allowed to void in the recumbent position during the study and in the standing position when the experiment had just been completed. Excreted volume of urine was recorded.

Venous blood (10 ml) was collected over 3 h. Samples were obtained every 5 min during the first 60 min and every 10 min thereafter. A tourniquet was not used. The first sample was obtained in duplicate and the mean value was used in calculations. Blood haemoglobin concentration (B-Hb) was measured on a Technicon H2 (Bayer, Tarrytown, NY, USA) using colorimetry at 546 nm. Serum albumin concentration was measured by dry chemistry based on the bromcresol green method followed by reflection spectrophotometry (Ektachem 250/950 IRC, Johnson and Johnson, Rochester, MI, USA). The duplicate samples

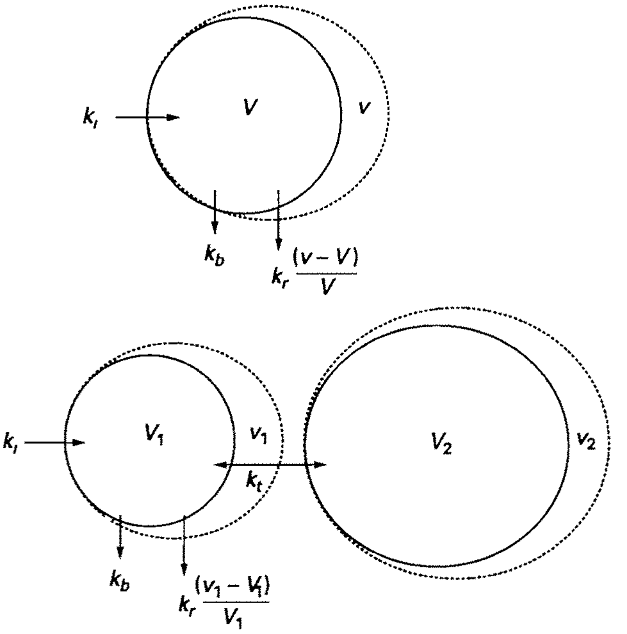

Figure 1 In the one-volume model (top), a fluid infused at a rate k_i is distributed in an expandable space with a volume (v), which the fluid space strives to maintain at an ideal (target) volume (V). Fluid leaves the space at a basal rate (k_b) and at a controlled rate proportional by a constant (k_r) to the deviation from the target volume. In the two-volume model (bottom), the primary fluid space communicates with a secondary fluid space. The rate of volume equilibration between the expandable fluid spaces (with volumes v_1 and v_2) is proportional to the relative difference in deviation from the target values (V_1 and V_2) by a constant (k_t).

obtained ensured a coefficient of variation of 1.0% for B-Hb and 2.7% for serum albumin.

The distribution of fluid given by i.v. infusion was analysed using volume-of-fluid-spaces kinetic models, which are summarized in figure 1. The infused fluid is assumed to occupy one or two expandable body fluid spaces and elimination occurs at a basal rate (perspiration and basal diuresis) and at a rate proportional to dilution of the central fluid space, V_1. The differential equations describing the volume changes in the expanded body fluid spaces and their matrix solutions are shown in the appendix.

Dilution of plasma volume (i.e. $(v_1—V_1)/V_1$), was used to quantitate fluid load. Plasma volume was chosen because extracellular fluid, but not erythrocytes, are expanded by the infused fluid. For this purpose, data on serum albumin were used directly. However, when the data on B-Hb were analysed, dilution of plasma volume was taken as the product of dilution of blood volume and (1–packed cell volume), where packed cell volume was assumed to decrease in proportion to the reduction in B-Hb. A correction for the loss of erythrocytes with blood sampling was always made.[1-3] The rate of spontaneous fluid loss from the expandable fluid space(s) (k_b) was set at 0.8 ml min^{-1}, which includes compensation for fluid loss associated with blood sampling. We have used previously a k_b value of 1.0 ml min^{-1}, but those volunteers ate a light meal before the experiments.[2]

The model parameters were calculated on a computer using Matlab version 4.2 (Math Works Inc., Notich, MA, USA) in which a non-linear least squares regression routine based on a modified Gauss–Newton method was repeated until no parameter changed by more than 0.001 (0.1%) in each iteration. Curve-fitting was performed on the one-volume fluid space model (VOFS1) where the output consists of the best estimates and standard errors for V and k_r. Calculations were then performed according to the two-volume fluid space model (VOFS2) where the output consists of the best estimates and standard errors for V_1, V_2, k_r and k_t. However, the results of VOFS2 were reported only if the F test indicated that it was statistically justified to fit a biexponential curve instead of a monoexponential one to the data.[5] An F value is obtained using the following equation:

$$F = [(MSQ_{VOFS1} — MSQ_{VOFS2})/MSQ_{VOFS2}] \times [df_{VOFS2} /(df_{VOFS1} — df_{VOFS2})]$$

where MSQ = mean square error for the difference between measured dilution of plasma volume and optimal curve fit according to VOFS1 and VOFS2, respectively; df = degrees of freedom, that is the number of data points used in fitting the function, minus the number of parameters fitted. The calculated value for F is compared with the critical value for significance in a standard statistical table.

All calculations were performed both when k_r was estimated together with the other parameters and also when k_r was set to a fixed value determined by

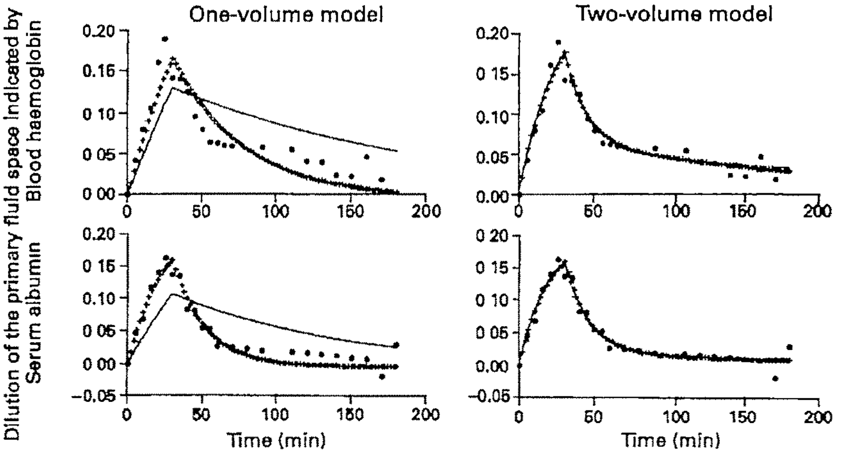

Figure 2 Volume kinetic curves from one experiment. When plasma dilution is indicated by both blood haemoglobin (top row) and serum albumin (bottom row) concentrations, the one-volume model (left) and the two-volume model (right) can generate a dilution–time curve using an elimination rate constant determined by the urinary excretion value (solid line) or by a value generated by the model (irregular line with crosses). In the latter case, the curves overlap although the model might give a lower k_r and a larger V_1.

Table 1 Kinetic analysis according to the one-volume fluid space model based on dilution–time data obtained during and after i.v. infusion of Ringer's solution 25 ml kg^{-1} over 30 min in 15 male volunteers. The first line for each variable gives the estimate and the second line its standard error. Data are median (25th and 75th percentiles). *Calculated from urine excretion. MSQ = Mean square error

total urinary excretion during the experiment. To calculate k_r, the excreted volume of urine was divided by the integral of the dilution–time curve after assuming that half of the spontaneous elimination of fluid (k_b) also appeared as urine.

Data are presented as median (25th and 75th percentiles). Differences between methods of analysis were studied by the Wilcoxon matched pair test and the Mann–Whitney *U* test, as appropriate. Correlations between parameters were evaluated by linear regression, where r = correlation coefficient. $P < 0.05$ was considered statistically significant. Five of the 15 experiments have been used in another report.[5]

Results

Dilution of B-Hb and serum albumin concentrations increased during the infusions and decreased promptly during the first 30 min after the infusion was completed. Thereafter, dilution was usually restored more slowly (fig. 2). Total urinary excretion was 950 ml (25th and 75th percentiles 718, 1067 ml, respectively).

Use of the urinary excretion value to calculate k_r markedly increased the mean square error (MSQ) obtained when the one-volume model was fitted to the data, when both B-Hb and serum albumin were used to indicate dilution of plasma volume (table 1, fig. 2). The target volume, V, and the standard error associated with this estimate, became larger. The model-predicted k_r was markedly higher than the k_r obtained from the urine data.

The two-volume model was also applied, and we report the experiments in which this model was statistically justified. Here, application of the urine excretion-generated k_r also increased MSQ, but the difference was not great (table 2). Little difference was seen when the two curve fits were compared graphically (fig. 2, right). The parameter standard errors were significantly reduced by applying a fixed k_r

Table 2 Analysis of the same data as in table 1 using the two-volume fluid space model. The experiments are reported in which the application of a biexponential curve instead of a monoexponential curve was statistically justified (partial *F* test). *Calculated from the urine excretion. MSQ = Mean square error

instead of allowing k_r to be estimated by the model, the only exception being the error associated with estimate of V_2. However, the error of V_2 became significantly reduced when the standard error *relative* to the size of V_2 (i.e. the standard error divided by V_2) was studied.

The difference between the fixed and model-generated values of k_r correlated inversely with the differences in target volumes (V or V_2) obtained in the same analyses; the regression line runs through zero in the plots for both the one-volume (fig. 3, left) and two-volume (fig. 3, right) models. The size of the model-generated V_2 is expected to be approximately 10 litre (130 ml kg^{-1}) when there is full agreement between the model-generated k_r and the value calculated from urinary excretion (fig. 4).

The experiments which generated data deviating markedly from the zero intercept in figure 3 were characterized by strong within-patient covariances between k_r and V_2 ($r^2 \leqslant -0.98$). When a solution to the two-volume model was obtained and the curve fit appeared to be statistically justified, such a high covariance between k_r and V_2 was found in four of the experiments based on dilution of serum albumin (table 3). In these cases, the absolute size of V_2 and the standard error associated with this estimate were much larger than in the other experiments.

Discussion

Volume kinetics may become an important tool to optimize fluid therapy in surgery and trauma care in the future.[1-4] This approach provides knowledge on how plasma volume expansion during and after i.v. infusion of fluid changes over time. For example, the values obtained for the model parameters in tables 1 and 2 can be entered into a computer and, using the mathematical solutions presented in the appendix, simulate the dilution–time profile after any infusion rate or combinations of infusion rates of Ringer's solution. Furthermore, as dilution stems only from the infused fluid, the size of the body fluid spaces expanded by crystalloid fluid and the rates of exchange of fluid between these spaces, under optimal conditions, may be close to the real volumes and rates.

This study was designed to evaluate if volume kinetic models can be made more stable by using the urinary excretion value as an input variable in the calculations. This might be achieved by calculating the elimination rate constant (k_r) from the excreted volume of urine and the area under the curve of the dilution of B-Hb or serum albumin concentrations during and after i.v. infusion of Ringer's solution.

However, the results showed that the models usually did not become more stable when this was done. In the one-volume model, the use of a fixed k_r increased the mean square error associated with the curve-fitting and the standard error involved in estimating the size of the single expanded body fluid space. This implies no benefit. The curve fit shown in figure 2 also illustrates clearly that the k_r fixed by urinary excretion was a poor estimator of the shape properties of the dilution curve. When the two-volume model was applied to the data, however, the shape of the dilution curve appeared very similar when the fixed and model-predicted values of k_r were used. The parameter standard errors became reduced when using a fixed k_r, but the improvements were approximately those expected when determining three parameters instead of four. Although significant, the improved precision was not large enough to warrant a new practice for performing these calculations.

There is one special situation, however, when the use of a fixed k_r seems to be warranted. When the *F* test indicates that the two-volume model is statistically justified but the conventional method of obtaining model-generated estimates of all four parameters shows a strong within-patient covariance between V_2 and k_r (r between −0.98 and −1.00), the size of V_2 is given with so poor a precision that the estimate does not contain any real information. In these cases, the model-generated value of k_r differs considerably from that indicated by urinary excretion. When this situation occurs, it would be justified to use urinary excretion to calculate k_r, because this is a better choice than to accept the optimal curve fit generated by the one-volume model. In our study, we found such strong covariances only when dilution of V_1 was indicated by serum albumin concentration, but in subsequent experiments we have confirmed that the "galloping" V_2 can be found also when B-Hb concentration is used.

Comparison between the values of V_2 and k_r obtained when using a fixed k_r offered some further theoretical basis for the "true" size of V_2. When the model-generated k_r differs from the fixed value, the size of V_2 is also likely to differ by a magnitude that is predictable. A plot of these differences indicates that the zero difference between the two analytical approaches corresponds to a size of V_2 of approximately 10 litre. This size should represent the most accurate estimate of the volume of the peripheral fluid space that is expanded by the infused fluid. However, our view is valid only if k_r represents urinary excretion and that the difference between the two values of k_r is correct.

The volume of 10 litre for V_2 was a few litres less than the expected size of the interstitial fluid volume, but is not unreasonable as the interstitial fluid space of the central nervous system and bone tissue can hardly be expanded by Ringer's solution. It should be emphasized that the size of an expandable fluid space can only be determined by expanding it. This volume is not available for measurement by tracer techniques. Although not elaborated upon in this study, the reader should observe that some experiments are better explained by a one-volume kinetic model than by a two-volume one, and that the total size of the expandable body fluid space in those cases is usually smaller compared with when the two-volume model is justified.[2 3]

The other parameters in the two-volume model were less affected than V_2 and k_r when the urinary excretion value was used as an input variable. The size of the primary (central) fluid space, V_1, was 3.4–4.3 litre, which suggests that it corresponds to plasma volume. These parameters were estimated with a standard error of approximately 10%, although the error was somewhat larger when k_r was generated by the model. The constant k_t, which governs diffusion of fluid between the primary and secondary fluid spaces, did not differ significantly depending on whether or not a fixed k_r was applied.

The problem with a strong covariance between V_2 and k_r stems in part from the choice of method used to perform the volume kinetic analysis. The first approach used was the random search method which tests different parameter values to minimize the squared difference (MSQ) between a model-generated curve and the experimental data.[1 2] The iterations continue until no further improvement of the fit is obtained in 15 trials. The second approach, which is based on matrix algebra to facilitate future modifications of the model, also repeats an algorithm until the MSQ is minimized. However, the model works by adding corrections to the previous parameter values, and the corrections are based on the derivative of a gradient function. No testing of random values is involved. The model continues to search for the optimal parameter values until none is changed by more than 0.1% in each iteration. The confidence interval for the minimum represents an ellipsoid area in the parameter space, and the precision of the parameter value can be poor if this area is very long and narrow.[3 4]

The "galloping" V_2 implies that the iterations continue with a progressive increase in V_2 and a decrease in k_r when MSQ is already very low. This problem did not occur with the random search method, but we have realized that the precision of V_2 given by this algorithm is always poor in the experiments where the Gauss–Newton method results in a "galloping" V_2. Thus there is a need for making the two-volume model more stable in certain experiments when the random search method is also used. Good precision of the parameter estimates is essential if we wish to improve our understanding of the real body fluid volumes and kinetic constants involved in the disposition of crystalloid fluid.

In summary, the urinary excretion value can be used to make the two-volume kinetic model more stable in cases where the correlation matrix indicates strong within-patient covariance between V_2 and k_r. This approach is not clearly justified in other situations.

Appendix

A fluid given by i v. infusion at a rate k_i is distributed in an expandable space with a volume (v), which the fluid space strives to maintain at an ideal (target) volume (V). Fluid leaves the space at a basal rate, representing perspiration and baseline diuresis (k_b, fixed at 0.8 ml min^{-1}), and at a controlled rate proportional by a constant (k_r) to the deviation from the target volume. The following differential equation describes the situation for the single-volume fluid space model (fig. 1, top):

$$dv/dt = k_i - k_b - k_r\,(v-V)/V$$

A two-volume space model was also developed in which the primary fluid space communicates with a secondary fluid space. The net rate of fluid exchange between the expandable fluid spaces (with volumes v_1 and v_2) is proportional to the relative difference in deviation from the target values (V_1 and V_2) by a constant (k_t) (fig. 1, bottom). Also, in the two-volume model, the system strives to maintain the target volumes by acting on the controlled elimination mechanism in proportion, k_r, to the relative deviation from the target volume of the primary fluid space. The following system of differential equations describes the situation:

$$\frac{dv_1}{dt} = k_i - k_b - \frac{k_r(v_1 - V_1)}{V_1} - k_t\left[\frac{(v_1 - V_1)}{V_1} - \frac{(v_2 - V_2)}{V_2}\right]$$

$$\frac{dv_2}{dt} = k_t\left[\frac{(v_1 - V_1)}{V_1} - \frac{(v_2 - V_2)}{V_2}\right]$$

The mathematical models describing the one-volume and two-volume models are linear differential equations with constant coefficients and their solutions can be given analytically in different forms. The single fluid space model is easily solved as a monoexponential solution.[1 4] The solution of the two-volume fluid space model used in this study is based on the matrix exponential e^{At}. During infusion (d) we have

$$\begin{pmatrix} w_{1d}(t) \\ w_{2d}(t) \end{pmatrix} = [(k_i - k_b)/k_r](I - e^{At}) \begin{pmatrix} 1 \\ 1 \end{pmatrix} \qquad 0 \leq t \leq t_1$$

and after infusion

$$\begin{pmatrix} w_{1a}(t) \\ w_{2a}(t) \end{pmatrix} = (-k_b/k_r)(I - e^{A(t-t_1)}) \begin{pmatrix} 1 \\ 1 \end{pmatrix} + e^{A(t-t_1)} \begin{pmatrix} w_{1d}(t_1) \\ w_{2d}(t_1) \end{pmatrix}$$

$$t_1 \leq t \leq \infty$$

where the matrix A is

$$A = \begin{pmatrix} -(k_r + k_t)/V_1 & k_t/V_1 \\ k_t/V_2 & -k_t/V_2 \end{pmatrix}$$

This form is well suited for numerical computation using, for example, the mathematical program Matlab, which has the matrix exponential e^{At} implemented as a standard function.

Bovine haemoglobin-based oxygen carrier for patients undergoing haemodilution before liver resection

T. STANDL, M.-A. BURMEISTER, E.-P. HORN, S. WILHELM, W. T. KNOEFEL AND J. SCHULTE AM ESCH

Summary

We have studied the use of ultrapurified polymerized bovine haemoglobin (HBOC-201) in patients undergoing preoperative haemodilution before liver resection. After autologous blood donation of 1 litre, 12 patients (six males, six females, mean age 59 (35–69) yr) received Ringer's lactate solution 2 litre and, in a random design, 6% hydroxyethyl starch 70 000/0.5 (HES) 3 ml kg^{-1} or HBOC-201 0.4 g kg^{-1} within 30 min. Blood samples were obtained for blood chemistry, co-oximetry, haematology, coagulation profiles and immunology examinations before operation, on the day of surgery, on days 2–4 and 7 after operation, on the discharge day and 3 months after operation. There were no differences in patient characteristics, blood loss, amount of solutions infused, transfused allogeneic blood or duration of hospital stay. There were no local or systemic allergic reactions with infusion of HES or HBOC-201. Patients receiving HBOC-201 developed more pronounced leucocytosis and reticulocytosis during the early postoperative days compared with HES-treated patients. The mean maximum plasma haemoglobin concentration was 1.0 (SD 0.2) g dl^{-1} at the end of infusion of HBOC-201. The mean intravascular half-life of HBOC-201 was 8.5 h. Patients in both groups experienced temporary changes in liver enzymes and coagulation variables which returned to normal before discharge. Urinalysis revealed no difference between groups and no free haemoglobin was detected in urine. Patients receiving HBOC-201 showed no IgE and only a slight increase in IgG titres to HBOC-201 on the day of discharge; these were not detectable at 3 months. Single-dose administration of HBOC-201 was well tolerated by patients undergoing elective liver resection surgery and appears to be safe as a substitute during preoperative haemodilution. (*Br. J. Anaesth.* 1998; **80**: 189–194)

Keywords: blood, substitutes; blood, replacement; blood, haemoglobin; fluids, i.v.; fluid therapy; blood, haemodilution; surgery, hepatic

Technical progress in the purification and formulation of haemoglobin solutions has resulted in the production of oxygen carriers which are free of toxic side effects on the liver and kidneys. Animal studies in different species have shown that a novel ultrapurified polymerized bovine-derived haemoglobin does not cause severe side effects on the liver, kidney or coagulation,[1 2] even in doses higher than those used clinically.[3] In addition, this bovine haemoglobin solution has a calculated relative potency of three times that of red blood cells (RBC) in restoring tissue oxygenation.[4] A phase I study in normal volunteers showed that polymerized bovine haemoglobin had a dose-dependent intravascular half-life of 16 h.[5]

Several studies have shown that patients with different tumours had a shorter disease-free survival and higher incidence of recurrent or metastatic cancer if they received perioperative allogeneic blood transfusions.[6 7] There is also evidence that the rate of postoperative infection is higher in patients after homologous red cell transfusion than in patients who were not transfused.[8] As a consequence, perioperative blood substitution with haemoglobin solutions may be advantageous in cancer patients by reducing the amount of allogeneic blood transfusions. As animal data indicate that bovine haemoglobin could enhance the amount of preoperatively donated blood[9] this material may have an indication in cancer patients who are normally excluded from predonation of autologous banked red cells.

This prospective, randomized study was designed to examine the safety and tolerance of a moderate dose of bovine haemoglobin compared with hydroxyethyl starch when used during acute preoperative blood donation in patients undergoing liver resection.

Patients and methods

After obtaining Ethics Committee approval and informed consent, we studied 12 patients (six males, six females, mean age 59 (range 35–69) yr, ASA I–II) undergoing elective liver resection surgery. Exclusion criteria were severe cardiovascular disease (e.g. uncontrolled hypertension >180/100 mm Hg, recent myocardial infarction <6 months, unstable angina, congestive heart failure), decompensated pulmonary disease or porphyria. Patients suffering from acute or chronical hepatic infections (e.g. hepatitis B and C), liver cirrhosis, anaemia (preoperative packed cell volume <30% or haemoglobin <10 g dl^{-1}) or allergic reactions to beef products were also excluded.

Phospholipid (nmol ml^{-1})		<3

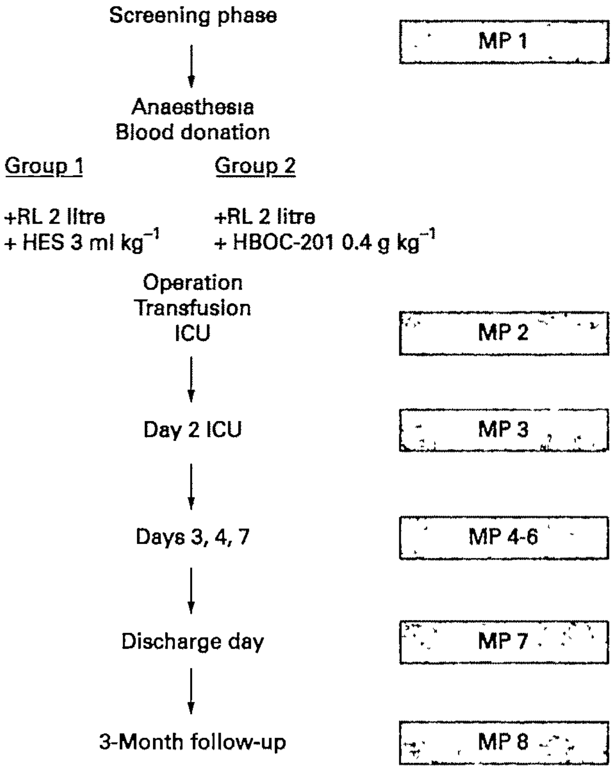

Figure 1 Study design. RL = Ringer's lactate solution; HBOC-201 = ultrapurified, glutaraldehyde polymerized bovine haemoglobin; HES = hydroxyethyl starch 70,000/0.5.

All patients underwent a screening examination 1–3 days before operation. On the day of surgery, patients were premedicated with midazolam 7.5 mg orally, 1 h before arriving in the anaesthesia room where they were monitored by ECG, non-invasive arterial pressure measurement and pulse oximetry. General anaesthesia was induced with fentanyl 3 µg kg^{-1}, etomidate 0.3 mg kg^{-1} and vecuronium 0.1 mg kg^{-1}. After tracheal intubation the lungs were ventilated mechanically with 70% nitrous oxide in oxygen. Anaesthesia was maintained with 0.6–0.8 vol% isoflurane and repeated i.v. injections of fentanyl 0.1 mg and vecuronium 2 mg.

Two large peripheral i.v. cannulae were inserted for autologous blood donation and infusion of the respective substitute. A radial cannula, central venous and urinary catheters were inserted. After autologous blood donation of 1 litre and infusion of lactated Ringer's solution 2 litre, patients received in a random manner within 30 min, hydroxyethyl starch (HES) 70,000/0.5 (Rheohes, B. Braun, Germany) 3 ml kg^{-1} (group 1) or ultrapurified, glutaraldehyde polymerized bovine haemoglobin (HBOC-201, Biopure, Cambridge, USA) 0.4 g kg^{-1} (group 2) (table 1).

Blood-gas tensions were measured with an ABL 505 (Radiometer, Denmark). Oximetry was performed using the OSM 3 (Radiometer, Denmark). Plasma haemoglobin concentrations were measured after 5 min of centrifugation (4000 rpm, Heraeus Sepatech) of arterial blood which was stabilized with ethylenediamine tetra-acetic acid (EDTA). Total haemoglobin concentration was also measured in EDTA-stabilized arterial blood by the haemoglobin cyanide method. Haematology, white blood cell differential and platelets were measured in a standardized blood smear of arterial EDTA-stabilized blood samples by microscopy. Coagulation variables (Quick's value, activated partial thromboplastin time (APTT) and fibrinogen) were measured by specific tests. A Hitachi 747 autoanalyser was used for measurement of blood chemistry. At every measurement time (MP 1–8), 10 ml of urine were aspirated from the urinary catheter and examined for free haemoglobin concentration, pH, glucose, protein, ketones, red and white cells, epithelial cells and casts. Immunological samples were obtained on the day before surgery, on postoperative day 7, on the day of discharge and 3 months after surgery.

Blood loss, and amount of crystalloids and colloids infused were monitored during operation and the amount of transfused allogeneic blood within postoperative days 1–7. All patients received their own donated blood when intraoperative haemoglobin concentrations were <7.5 g dl^{-1} or at the end of operation. Duration of postoperative artificial ventilation in the ICU and duration of hospital stay were recorded.

All measurements were performed before surgery (MP 1), 4 h after surgery in the ICU (MP 2), on the morning of postoperative days 2–4 and 7 (MP 3–6), and on the day of discharge (MP 7). A follow-up examination was performed 3 months after operation (MP 8) (fig.1).

Data are reported as mean (SD). Patient data in both groups were tested by the Mann–Whitney *U* test. Differences within groups were tested by ANOVA for repeated measurements and *post hoc* comparison by Student's *t* test. Differences between groups were tested by the Wilcoxon test or two-way ANOVA and *post hoc* Bonferroni's correction for alpha. All differences were considered significant at $P < 0.05$.

Results

Patient characteristics and data on perioperative fluid management are given in table 2. After autologous

blood donation, patients in group 1 received HES 241 (29) ml and in group 2 HBOC-201 233 (44) ml. No local or systemic allergic reactions were detected during infusion of HES or HBOC-201. Two patients in each group underwent resection of one or two liver segments; two patients in group 1 and three patients in group 2 received a left or right hemi-hepatectomy. Because of unexpected tumour spread, resection was not possible in two patients in group 1 and in one patient in group 2.

There were no differences in heart rate, ventilatory frequency, temperature, pulse oximetry or blood-gas tensions between groups at any time. However, on admission to the ICU (MP 2), patients in group 2 had a higher mean arterial pressure than those in group 1 (95 (18) *vs* 83 (11) mm Hg; $P = 0.037$).

Plasma haemoglobin concentration peaked at 1.0 (0.2) g dl^{-1}, 30 min after the start of infusion of HBOC-201 and showed a decrease to 0.22 (0.1) g dl^{-1} on the morning of day 2 (table 3). The extrapolated intravascular half-life of HBOC-201 was 8.5 h.

In contrast with group 1, the concentrations of total arterial methaemoglobin increased after operation in group 2 with the maximum on day 2. The increase in leucocytes on postoperative days 2–4 and reticulocytosis on day 3 were more pronounced in the HBOC-201 group compared with baseline values than in the HES group (table 3).

Haemodilution and operation-dependent decreases in coagulation occurred; these returned to baseline values within 7 days after surgery (table 4). There were no differences between groups.

There were no differences in blood chemistry between groups (table 4, figs 2–4). All HES patients were negative for both IgG and IgE to HBOC-201. No IgE antibody responses to HBOC-201 were detected in group 2. Five of six patients in group 2 developed clinically insignificant titres to HBOC-201, and IgG was undetectable 3 months after infusion.

Urinary output did not differ between the two groups during the early postoperative period. Free

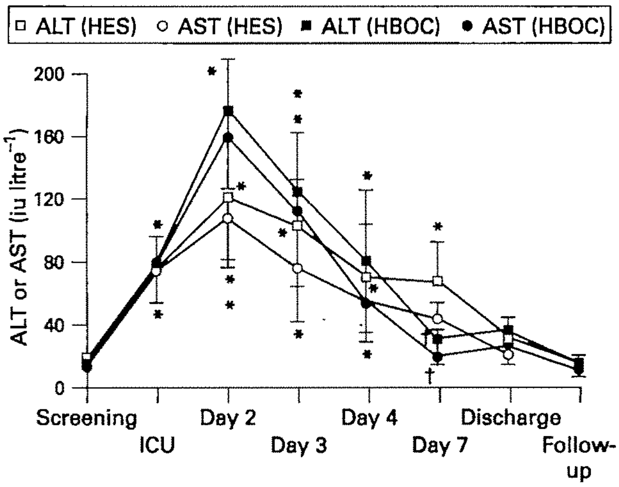

Figure 2 Changes in concentrations of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) after preoperative haemodilution with HES or HBOC-201 in liver resection patients. Values are mean (SEM). $*P < 0.05$ *vs* screening; $\dagger P < 0.05$ *vs* HES.

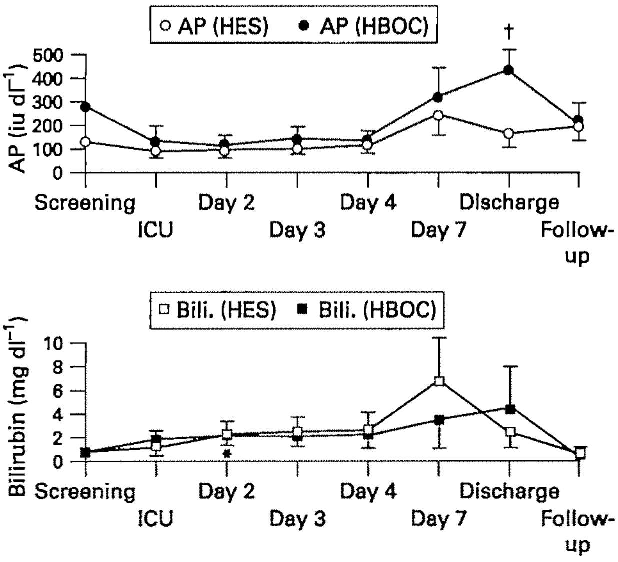

Figure 3 Changes in concentrations of alkaline phosphatase (AP) and bilirubin (Bili.) after preoperative haemodilution with HES or HBOC-201 in liver resection patients. Values are mean (SEM). $*P < 0.05$ *vs* screening; $\dagger P < 0.05$ *vs* HES.

haemoglobin was not detected in urine over time. Urinalysis did not change in comparison with baseline and there were no differences between groups.

Duration of artificial ventilation was 360 (326) min in group 1 and 245 (317) min in group 2 ($P = 0.55$). Duration of hospital stay was 12.5 (8) days in group 1 and 14.8 (9.3) days in group 2 ($P = 0.66$). Major adverse events were seen in three patients in group 1 and in two patients in group 2. Adverse events included hyperbilirubinaemia (caused by stenosis of the hepatic duct which required operative revision) and increased serum amylase without clinical pancreatitis in group 1, and atelectasis and hepatic insufficiency (on postoperative day 4 after right hemihepatectomy in a patient with a fatty liver who underwent chemotherapy 4 weeks before operation) in group 2. No adverse event was considered to be associated with donation of HES or HBOC-201. With the exception of the one patient who died of multi-organ failure after hepatic insufficiency 4 weeks after operation, all patients were in excellent condition at the follow-up examination.

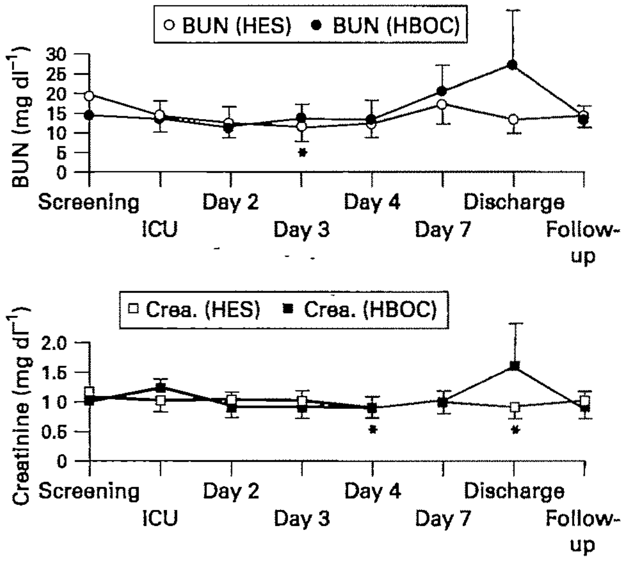

Figure 4 Changes in concentrations of blood urea nitrogen (BUN) and creatinine (Crea.) after preoperative haemodilution with HES or HBOC-201 in liver resection patients. Values are mean (SEM). $*P < 0.05$ *vs* screening.

Discussion

We have shown that a chemically modified ultrapurified bovine haemoglobin administered during preoperative haemodilution was tolerated well in patients undergoing liver resection surgery. However, the study failed to show any advantage of HBOC-201 compared with HES in terms of a sparing effect of allogeneic blood administration in these patients undergoing major abdominal surgery. One explanation for this result is the relatively small dose of HBOC-201, which appears to be too low for perioperative blood substitution in cases of massive blood loss. As the intravascular half-life of haemoglobin appears to be dependent not only on stabilization of the tetramer[10 11] but also on the dose of the haemoglobin solution given,[12] a single dose of HBOC-201 0.4 g kg^{-1} might have resulted in a shorter intravascular life in this study than has been reported in a dose-escalating study with this material.[5] In addition, intraoperative blood loss and perioperative infusions may have diluted the intravascular concentration of bovine haemoglobin. Disappearance into the interstitial and lymphatic space via diffusion has also been reported for intra-molecularly stabilized haemoglobin tetramers.[13] However, the intermolecular stabilization of HBOC-201 with glutaraldehyde resulted in haemoglobin polymers with a molecular size of 64 000–500 000 Da, which is greater than with intra-molecular haemoglobin stabilization and should preclude rapid excretion of this material into the interstitium.

As no free haemoglobin could be detected in urine over time, there is evidence that HBOC-201 was cleared by the reticuloendothelial system (RES). Animal studies have shown that either intra- or intermolecular stabilization of haemoglobin tetramers prevents rapid renal elimination.[14-16] However, a high molecular weight provided by polymerization may enhance uptake into the RES.[17] The effect that some of the haemoglobin formulations may have on the RES is unclear at present. Although there are animal data which described immunosuppressive effects when tetrameric human-derived haemoglobin solutions were given in a model of bacteraemia[18] or in combination with endotoxin,[19] there are no clinical data to suggest that immunosuppression occurs in humans. Our patients showed a transient leucocytosis and reticulocytosis after administration of HBOC-201 but bilirubin concentration was not higher compared with patients who received HES. No clinical correlate for immunosuppression, for example fever, delayed wound healing or concomitant infectious diseases, occurred in our study. However, the number of patients in this study was too small to allow conclusions on side effects of HBOC-201 on the immune system.

The early reticulocytosis on day 3 after operation which was observed in patients after administration of bovine haemoglobin may accord with the uptake of the compound by the RES where it possibly contributes to enhanced production of reticulocytes because of an increased iron supply by HBOC-201.[20]

We have shown that administration of a low dose of HBOC-201 had no toxic side effects on the liver, kidney, pancreas or coagulation, even in patients undergoing liver resection who are very sensitive to toxic influences on these respective organs. Liver enzymes increased to an extent which did not differ from values of patients treated with HES. All results were within the range which normally occurs after liver surgery.[21] As animal data have shown that organ toxicity of some haemoglobin solutions may be a function of impurities[22] we did not expect severe side effects on the liver, kidney or coagulation using an ultrapurified haemoglobin preparation. In contrast with an earlier applied stroma-free haemoglobin solution which resulted in impaired renal function as a result of clinically relevant concentrations of endotoxin and phospholipids,[23] endotoxin and phospholipids in HBOC-201 are undetectable.

One common problem with the use of haemoglobin solutions is oxidation of the free oxyhaemoglobin to methaemoglobin which does not contribute to oxygen transport. This may occur *in vitro* during storage and also *in vivo* after infusion. The HBOC-201 solution has a shelf-life of more than 2 yr when stored at room temperature and contains a maximum methaemoglobin concentration of $\leqslant 10\%$ if the bags are not damaged. However, after the material was given to patients, the fraction of methaemoglobin increased slightly in the HBOC-201 group but was still within the physiological range. It is therefore unlikely that this moderate increase in total methaemoglobin fraction is clinically relevant. Even after a dose of HBOC-201 45 g, the methaemoglobin concentration did not exceed 1.8% in volunteers.[24] HBOC-201 in the oxy-state possesses a very low oxygen affinity which is regulated by chloride ions and not by 2,3-DPG [25] and has been demonstrated to provide adequate tissue oxygen tensions in a model of nearly complete blood exchange.[26] In addition, plasma oxygen transport by HBOC-201 was able to normalize reduced post-stenotic skeletal muscle tissue oxygenation.[27]

The increased oxygen off-loading capacity is a primary property of HBOC-201 and is associated with compensatory haemodynamic changes in order to maintain normal tissue oxygen tensions.[28] Haemoglobin solutions have also been described as having a vasoconstrictive effect as a result of binding of nitric oxide,[29] [30] manifested by increased systemic vascular resistance and possibly by reduced blood flow to specific organs.[31] However, animal data indicate that autoregulatory mechanisms can override vasoconstriction *in vitro*, for example on coronary arteries.[32] In a rat model, Gulati, Sharma and Burhop[33] showed that chemically modified (e.g. diaspirin cross-linked) haemoglobin did not alter organ blood flow.

Vasoconstriction with increased mean arterial pressure (MAP) and decreased cardiac output has been demonstrated in patients undergoing preoperative haemodilution with HBOC-201 before vascular surgery.[34] This is consistent with our findings of an increased MAP on admission of patients to the ICU. Although there is no evidence that the vasoconstrictive effect of haemoglobin solutions is dose dependent,[35] no haemodynamic differences were seen in this study on day 2 after operation or later.

It is unclear if haemoglobin solutions also increase gastrointestinal smooth muscle tone. However, there was no evidence of an increased incidence of gastrointestinal adverse events or increased pancreatic sphincter tone in the HBOC-201 group as pancreatic amylase and alkaline phosphatase were not higher than values in HES-treated patients.

All major complications were considered not be associated with either HES or HBOC-201. It is known from the literature that liver resection carries a high rate of postoperative complications.[36]

Although all haemoglobin formulations are composed of modified haemoglobin with some immunogenic potential, administration of HBOC-201 was not associated with allergic reactions. However, the study of Hertzman, Keipert and Chang[37] revealed antigenic properties of polyhaemoglobin while other animal studies suggested low antigenicity of purified and chemically modified haemoglobin.[38–40]

Blood salvage during Caesarean section

M. P. Rainaldi, P. L. Tazzari, G. Scagliarini, B. Borghi and R. Conte

Summary

The aim of this study was to assess blood salvage during Caesarean section. In 15 Caesarean sections, red cells lost were collected and washed with a Dideco machine and tested for the presence of fetoplacental material, bacterial contamination, free haemoglobin and fetal blood cells. Successive patients were allocated randomly to one of two groups. In group 1 (n = 34), intraoperative blood was salvaged, while group 2 served as a control. The mean amount of blood salvaged in group 1 was 363 (SD 153) ml. Blood was salvaged following these guidelines: identification of blood group of the mother and fetus; avoidance of aspirating blood from the umbilical cord; commencement of salvage after removing the fetoplacental unit; completely filling the centrifugation bowl with red cells; washing the cells using at least 1000 ml of physiological solution per bowl; and mixing the contents of the bowl, completely eliminating the buffy coat where fetal cells are located. In group 1, the use of homologous blood transfusions was significantly lower (one of 34 (2.9%) patients compared with eight of 34 (23.5%); $P = 0.01$), haemoglobin concentrations during the first 4 days after operation were significantly higher and postoperative hospital stay was significantly shorter. Duration of hospital stay was significantly shorter in group 1 (5.3 (1.9) *vs* 7.3 (4) days; $P = 0.003$). Mean base haemoglobin concentrations were significantly lower in group 1 (10.7 (1.4) *vs* 11.7 (1.5) g dl^{-1}; $P > 0.0001$), while after surgery mean haemoglobin concentrations were significantly higher approximately 3 h after operation compared with the control group (10.2 (1.5) *vs* 8.6 (1.2) g dl^{-1}; $P < 0.0001$). On the first day, haemoglobin concentrations were 9.8 (1.5) *vs* 8 (1.4) g dl^{-1} ($P < 0.0001$), on the second day 9.8 (1.4) *vs* 7.7 (1.4) g dl^{-1} ($P < 0.0001$), on the third day 10.1 (1.5) *vs* 7.5 (1.3) g dl^{-1} ($P < 0.0001$) and on the fourth day 10.4 (1.5) *vs* 8.1 (1.4) g dl^{-1} ($P < 0.0001$). Keywords: surgery, obstetric; blood, transfusion; blood, replacement; blood, salvage

Counselling of pregnant women on the possibility of autologous blood donation before delivery to avoid any risk to the fetus is unusual.[1] Long-term freezing of autologous blood is possible, but this is not readily available for every pregnant woman. Thus in selected patients undergoing Caesarean section, it may be useful to ascertain the possibility of re-infusing intraoperatively salvaged blood, providing there is evidence that recovered red cells are devoid of contaminants, and major antigenic incompatibilities are avoided (AB0, Rh, Kell). Some studies have been reported: in 1989 a French group described blood salvage in 15 patients undergoing Caesarean section using the Hemonetics "Cell Saver 4" which washes cells without mixing the contents of the bowl.[2] The results showed that: free Hb increased by 20-fold; cultures for *Epidermis staphylococcus* were positive; fetal red cells were present in 20% of cases; and fetal lanugo and scales were found in one case.

Between 1989 and 1991 at Buon Samaritano Hospital, San Jose (CA, USA), four patients giving birth received a total of 9 u. of washed and salvaged blood without amniotic embolism or other complications attributed to re-infusion.[3]

The aim of this study was to assess blood salvage during Caesarean section and the effect of this procedure on perioperative haemoglobin concentrations and postoperative hospital stay.

Patients and methods

All patients gave written informed consent to the study which was approved by the Ethics Committee of the hospital. We studied 68 patients, mean age 32.7 (16–43) yr, body weight 72.5 (SD 11.6) kg and height 160.4 (5.7) cm who were allocated randomly to one of two groups. In group 1 (n = 34) mean age was 33.6 (22–43) yr, body weight 73.3 (SD 12.8) kg, height 161 (SD 5.9) cm, and blood lost during surgery was re-infused. In 17 cases of maternofetal blood group incompatibility, blood was re-infused after ensuring that no fetal blood was present. In group 2 (n = 34), mean age was 31.9 (16–41) yr, body weight 71.6 (SD 10.5) kg, height 160 (5.5) cm, and intraoperative blood loss was not salvaged.

In 43 patients the anaesthetic technique used was combined spinal extradural anaesthesia (elective surgery; 22 patients in group 1), in 12 spinal (urgent; six patients in group 1) and in 13 general anaesthesia (six patients in group 1; extremely urgent).

Blood was salvaged using the Dideco machine (Mirandola, Modena, Italy) which provides good

Placental detachment	3	2	1

quality washing because red blood cells can be mixed in the bowl during washing.[4 6] In order to limit contamination, blood salvage was started after extraction of the fetoplacental unit (i.e. during the most "bloody" but "cleanest" phase of the operation when the uterine cavity was open with the blood vessels gaping). Blood enters the aspirator where salvaged blood is mixed with anticoagulant solution (ACD formula A) then, through the connection tubes, to a reservoir where is passes through a 40-micron filter.[4] An adjustable speed peristaltic pump discharges anticoagulated blood to the centrifugation bowl where it is washed with isotonic solution and concentrated.[4 5] The best quality wash is obtained by alternating washing the red blood cells with mixing the bowl contents and reducing centrifugation speed to less than 1000 rpm.[4 6]

To assess the quality of these red cells, in 15 patients blood was salvaged, not re-infused, but subjected to a series of quality tests.

(1) Culture and microbiological tests.

(2) Free haemoglobin in supernatant blood using the Technycon Bayer H2 optic laser globule counter and a photometric method.[7]

(3) Evaluation of fetal haemoglobin with the HPLC DIAMAT (Biorad) automatic system (20 µl of haemolysed blood were introduced in the cationic exchange silica gel chromatographic column which separates haemoglobin by tampons with progressively increasing ionic strength and pH, enabling elution of haemoglobin by the column at a precise, standard time). Fetal haemoglobin elutes at 3.5 min and a filtered photometer reads the fractions eluted at 415 and 690 nm and a computer performs the integration of the chromatogram peaks.[8 9]

(4) Microscopic slide examination of blood salvaged and washed, and stained using the May–Grunwald–Giemsa method.

(5) Assessment of procoagulant activity of placental origin in the supernatant from salvaged and washed blood. The whole of each sample was tested after microfiltration (this liquid was added in equal parts to a pool of normal plasma). The results were compared with those obtained by adding, in the same proportion, tampon PBS pH 7.4 to the pool of normal plasma. Three different tests were: addition of $CaCl_2$ 0.025 mol litre^{-1}, addition of kaolin 5 g litre^{-1} and addition of APTT reagent diluted 1:50 (containing homogenized human platelets and kaolin).

(6) Fetal red blood cell contamination evaluated by cytofluorimetry for fetomaternal incompatibility (ABO, Rh). In these cases, fetal haemoglobin was not determined.

(7) Assessment of blood groups. EDTA-containing samples from mother and umbilical cord (fetus) were analysed immediately after delivery for A, A1, B, D, C, c, E, e, K and k antigens using standard methods (Kell-incompatibilities were not found).

(8) Evaluation of the presence of fetal red blood cells in salvaged blood in case of ABO or Rh incompatibility, or both. Erythrocyte antigen expression was studied by immunofluorescence and flow cytometry[10–13] and different polyclonal antisera were used, according to the fetal antigenic mosaic.[14]

In 17 patients with ABO incompatibilities, we used hyperimmune anti-A and anti-B antisera with an IgG titre >1:512 diluted appropriately in saline; in patients with Rh incompatibility, the following reagents were used: anti-D (Ortho Diagnostic System, Raritan NJ, USA) and anti-D, anti-C, anti-c anti-E and anti-e (A. Menarini Diagnostici, Firenze, Italy). All antisera were approved for slides and test tubes. Fluorescein–isothiocyanate conjugated rabbit anti-human IgG immunoglobulins were used as a second-step reagent.

A standard immunofluorescence technique was used, as described previously. The fluorescence intensity of each sample was evaluated using a Coulter EPICS XL-MCL cytofluorimeter (Coulter, Hialeah, FL), equipped with a 488 mm air-cooled argon laser. An electronic bit-map gating for red blood cells was set by combining forward scattering (log scale) with 900 light scattering (linear scale) and the percentage of positive erythrocytes was evaluated both by histograms with log-integrated green fluorescence, plotted against the number of red cells counted (10 000 at least) and by plotting green fluorescence analysis against forward scattering. Histograms and MCV values were generated by the standard software of the EPICS XL MCL-dedicated computer.

Indications for Caesarean section, co-existing diseases, perioperative haemoglobin concentrations, intra- and postoperative complications, and duration of hospital stay were recorded for all patients (tables 1, 2). Statistical analysis was carried out using contingency table tests, Fisher's test, ANOVA and the Mann–Whitney test.

Results

Our quality tests on salvaged blood revealed that: the culture and microbiological tests were negative; fetal haemoglobin was absent, except in three patients in which it was 1.8–2.0%. In these three patients fetal haemoglobin was also present in maternal blood (1.5–1.8%) which confirms transplacental passage of fetal haemoglobin during pregnancy; free haemoglobin was virtually absent (mean 0.05 (SD 0.06) mg %); fetoplacental material was not observed on

Table 3 Use of homologous red blood cells (HRBC) and duration of postoperative hospital stay (number (%) or mean (SD) [range]) in both groups

microscopy. Leucocytes and cell fragments were detected only in cases where the buffy coat had not been eliminated completely; and study of procoagulant activity in salvaged blood revealed a normal recalcification time in 13 of 15 patients. In two samples, where during salvage the buffy coat was not removed totally because of incomplete filling of the bowl, recalcification time was shortened (compared with the pool and tampon). This shortening was eliminated by removing the fragments of lysed cells (red cells, white cells, amniotic cells) and filtration of the supernatant.

The presence of fetal blood, tested by cytofluorimetry in all cases with maternofetal blood group incompatibility, was found in a quantity of 0.8–1.4% in four patients who did not receive re-infusion of blood. The cause of this contamination was errors in carrying out the salvage procedure, such as aspiration of blood from the umbilical cord and incomplete removal of the buffy coat in the washing technique produced by incomplete filling of the bowl.

The two groups were similar in age, height and body weight. The mean amount of blood salvaged in the 34 patients who underwent re-infusion was 363 (SD 153) (range 125–800) ml. Mean packed cell volume of re-infused red blood cells was 62 (SD 5) %. Five days after surgery, one of these patients received transfusion of 2 u. of homologous blood because of persistent anaemia (with symptoms of dizziness on assuming an upright position). In the second group, eight patients received homologous blood transfusions between the first and fifth day. The use of homologous transfusions (table 3) was significantly different in the two groups (contingency tables with Fisher's test, $P = 0.01$).

In patients in whom blood salvage was carried out, mean basal haemoglobin concentrations were significantly lower than those in group 2 patients (ANOVA, $P = 0.001$), while mean postoperative haemoglobin concentrations 3 h after surgery, on day 1, 2, 3 and 4 after operation were significantly higher (ANOVA, $P < 0.0001$) (fig. 1).

Postoperative complications in group 1 included cystitis with pyrexia (one patient) and subfascial parietal haematoma (one patient). In group 2, complications included hyperpyrexia after transfusion of homologous blood following persistent mild fever and discharge against the doctor's advice (two patients), and pulmonary oedema and ascites needing intensive care for 4 days (one patient). There were no complications as a result of re-infusion of salvaged blood cells.

With regard to postoperative hospital stay (table 3) because the SD value in the two groups differed considerably, ANOVA could not be used, and therefore the mean rates of the Mann–Whitney tests were used. This test revealed that hospital stay was significantly shorter ($P = 0.003$) in group 1.

Discussion

We have demonstrated that in the absence of contaminants and antigenic incompatibilities caused by fetal red blood cells, salvaged blood was re-infused safely.

The increasing use of surgery in childbirth and the subsequent need for blood transfusion, together with patients' reluctance to receive homologous blood transfusions, is posing problems for the anaesthetist. Predepositing blood is still experimental and not performed routinely in obstetric surgery for several reasons: (1) fear of removing excess amounts of blood because of possible repercussions on uterine and fetal activity, as reported in the literature[1]; (2) varying degrees of anaemia in at least 50% of cases; (3) difficulty in predicting the date of childbirth, even by surgical intervention (planned Caesarean section brought forward because of concerns regarding fetal wellbeing); and (4) limited usefulness in patients with severe haemorrhage.

Acute preoperative isovolaemic haemodilution is difficult to perform because of the physiological haemodilution present in the pregnant patient. We observed a higher postoperative haemoglobin concentration in patients who underwent intraoperative salvage and this confirms the findings of Orr and Blenko,[15] who reported a higher osmotic resistance than homologous banked blood cells, and McShane and colleagues,[16] who observed a higher concentration of 2,3 diphosphoglycerate, a more physiological concentration of potassium and pH, and a higher content of haemoglobin in blood washed with the Dideco Autotrans BT 795 compared with donated blood. Later, Alleva and colleagues[17] reported less damage to red cells salvaged during operation with the Dideco STAT and cells recovered after operation with the Dideco BT 797 Recovery compared with cells predeposited in SAG-M and preserved in the refrigerator for 21 days at 4 °C. We conclude that blood salvage may be useful to avoid autologous blood transfusion and it may be associated with a better outcome and shorter hospital stay.

Blood salvage during Caesarean section may be performed according to these guidelines: determine the blood group of the mother and fetus; avoid aspiration of blood from the umbilical cord; start salvage after removing the fetoplacental unit; completely fill the centrifugation bowl with red cells; wash the cells accurately using at least 1000 ml of physiological solution per bowl; and mix the contents of the bowl completely to eliminate the buffy coat where fetal cells are located

By following these guidelines we have obtained salvaged blood without fetal red cells or with minimal contamination of fetal elements, which may be re-infused even when maternofetal blood groups are incompatible.

If a pregnant woman is transfused with homologous blood at the end of delivery there is a risk of receiving incompatible Fy and Jk antigens. The highest estimated contamination of fetal blood, if present, in our procedure should be about 3 ml, which is in the range of spontaneous fetomaternal haemorrhage.[14] Thus in our study the risk of alloimmunization from the presence of fetal red cells in salvaged blood is as likely as in a normal delivery and problems caused by administration of homologous blood is avoided. Moreover, where fetomaternal D-antigen incompatibility exists, giving the patient Rh immune globulin (300 μg) may prevent sensitization to 15 ml of packed D positive red blood cells.

Prevention of spinal anaesthesia-induced hypotension in the elderly: i.m. methoxamine or combined hetastarch and crystalloid

D. J. BUGGY, C. K. POWER, R. MEEKE, S. O'CALLAGHAN, C. MORAN AND G. T. O'BRIEN

Summary

We have compared two methods of reducing hypotension during spinal anaesthesia in elderly patients, 6% hetastarch and crystalloid or methoxamine 10 mg i.m., in terms of haemodynamic stability and requirements for additional vasopressors. Sixty-two patients (aged 60–97 yr) undergoing surgical fixation of fractured neck of femur were allocated randomly to receive 6% hetastarch (Hespan) 500 ml followed by Hartmann's solution 500 ml (group HS, $n = 32$) or a bolus injection of methoxamine 10 mg i.m. (group MX, $n = 30$), 10 min before induction of spinal anaesthesia with 0.5% hyperbaric bupivacaine 2.25–3.0 ml. Arterial pressure was measured non-invasively by an oscillotonometer at 2-min intervals from 0 to 40 min and at 5-min intervals thereafter. Methoxamine 2 mg i.v. was given if systolic arterial pressure (SAP) decreased to <100 mm Hg. Hypotension was defined as a 25% decrease from baseline SAP or mean arterial pressure (MAP). Patient data, sensory level and blood loss were similar in the two groups. SAP and MAP increased initially from baseline until induction of spinal anaesthesia and then decreased for 30 min in both groups, but remained higher in group MX ($P < 0.05$). Heart rate (HR) decreased from baseline in group MX ($P < 0.05$) and was less than in group HS at all times from 2 to 60 min ($P < 0.01$). The incidence of SAP hypotension (47% *vs* 75%; $P = 0.03$, odds ratio (OR) = 3.43) and MAP hypotension (47% *vs* 67%; $P = 0.09$, OR = 2.51) was less in group MX than in group HS. Requirements for rescue methoxamine i.v. (27% *vs* 53%, $P = 0.04$, OR = 3.11) was less in group MX than in group HS but the dose of rescue methoxamine given (mean 6.3 (95% confidence intervals 3.0–9.6) *vs* 8.9 (5.6–12.2) mg) and time to onset of hypotension (20.7 (14.5–26.7) *vs* 17.3 (11.4–23.1) min) were similar in groups MX and HS, respectively. We conclude that methoxamine 10 mg i.m., given 10 min before induction of spinal anaesthesia in normovolaemic elderly patients, reduced subsequent SAP and MAP hypotension, HR and requirements for rescue vasopressor therapy compared with a combination of 6% hetastarch 500 ml and crystalloid 500 ml. The previously reported benefit of such volume administration may not extend to the elderly. (*Br. J. Anaesth.* 1998; **80**: 199–203)

Keywords: anaesthesia, subarachnoid; complications, hypotension; fluids, i.v.; fluid therapy; sympathetic nervous system, methoxamine.

Systemic hypotension is the most common complication of spinal anaesthesia, with an incidence of 25–82% in the elderly.[1–3] Despite no prospective outcome data, it seems reasonable to be concerned that the elderly may be at increased risk of long-term complications from hypotension occurring during spinal anaesthesia, because of reduced physiological reserve and atherosclerosis, particularly coronary artery disease.[3] A retrospective study suggested that patients who became hypotensive during anaesthesia had a five-fold increased risk of perioperative myocardial infarction compared with patients who did not develop hypotension.[4]

Strategies for treating spinal anaesthesia-induced hypotension include i.v. volume administration, which increases circulating volume and cardiac output in an effort to compensate for the expansion of the capacitance vessels, or pharmacological reversal of the reduction in systemic vascular resistance which inevitably accompanies spinal anaesthesia, using vasopressor agents.[5]

The practice of volume loading, that is rapid infusion of crystalloids before induction of spinal anaesthesia, dates from 30 yr ago, in which such infusions apparently reduced the high incidence of hypotension in obstetric patients.[6 7] More recent work from this decade has cast doubt on the efficacy and benefit of this practice. Several studies in women undergoing spinal anaesthesia for Caesarean section or tubal ligation have found that volume administration produces marginal, if any, reduction in the incidence of hypotension[8–10] while also causing significant increases in central venous pressure, pulmonary oedema and haemodilution, which may potentially have detrimental consequences.[10–12] In a recent investigation comparing crystalloid, gelatin colloid and no volume administration for spinal anaesthesia in an elderly population, we found that withholding of fluids was not associated with any greater incidence of hypotension or ephedrine use than the use of either crystalloid or colloid volume administration.[13]

However, volume administration with a combination of 6% hetastarch as synthetic colloid and crystalloid, in equal proportions, has been shown to

DONAL J. BUGGY*, MSC, MRCPI, DME, FFARCSI, CAMILLUS K POWER, MD, MRCPI, FFARCSI, RODNEY MEEKE, MSC, FFARCSI, SHEILA O'CALLAGHAN, FFARCSI, CIARAN MORAN, FFARCSI, GREGORY T O'BRIEN, FRCA, Department of Anaesthesia, Cork University Hospital, Wilton, Cork City, Ireland Accepted for publication: September 9, 1997.

*Address for correspondence: Senior Lecturer in Anaesthesia, Leicester University Department of Anaesthesia, Leicester General Hospital, Gwendolen Road, Leicester LE5 4PW.

produce significantly less hypotension than an equal volume of crystalloid or colloid alone in parturients.[11] [12] Whether this regimen would be effective in the elderly is unknown. Hetastarch 6% in 0.9% saline is a synthetic colloid derived from amylopectin, with a molecular weight of 450 000. Its pH is 5.5, osmolarity 310 mosmol litre^{-1} and its intravascular half-life is 25 h. Anaphylactoid reactions are less frequent than with other synthetic colloids, but it is expensive (approximately £30 per 500 ml compared with £0.65 for 1 litre of crystalloid) and may induce coagulopathy.[14] [15]

The alternative strategy for management of spinal anaesthesia-induced hypotension is the use of vasopressor agents, of which the most popular is ephedrine, a combined alpha and beta adrenergic agonist. However, the unreliability of its vasoconstrictive efficacy and its tendency to cause a positive chronotrophic effect on the heart have raised doubts about its safety in elderly patients.[16] [17] It makes physiological sense to use an alpha adrenergic agonist, such as methoxamine, which would pharmacologically reverse undesirable peripheral vascular dilatation, maintaining systemic arterial pressure, while avoiding unwanted cardiac effects. Metaraminol is the only commonly used pure alpha adrenergic agonist that has been investigated specifically during spinal anaesthesia in an elderly population.[18] These agents may be given by continuous infusion, but this requires an infusion pump, which may be too cumbersome for routine use, and has the potential for hazardous errors in its administration.

In this study, we have evaluated the incidence and onset time of hypotension and need for further vasopressor therapy in an elderly population given one of two prophylactic measures designed to minimize spinal anaesthesia-induced hypotension: methoxamine 10 mg i.m. or a 1-litre volume administration regimen comprising 6% hetastarch 500 ml and Hartmann's solution 500 ml.

Patients and methods

After obtaining Institutional Ethics Committee approval and informed consent, we studied 65 ASA I, II or III patients (aged 60–96 yr) undergoing emergency hip surgery (insertion of Austin–Moore prosthesis or dynamic hip screw). Exclusion criteria were ASA IV or V patients, uncontrolled hypertension (i.e. SAP >160 mm Hg) or congestive cardiac failure, clinical evidence of significant dehydration (reduced skin turgor, dry mucous membranes, systolic arterial pressure <100 mm Hg, Na^+ > 145 mmol litre^{-1}, urea >10 mmol litre^{-1}), those aged less than 60 yr and those for whom spinal anaesthesia was contraindicated. Patients were not premedicated, but all received continuous infusion of crystalloid as maintenance fluids (1.5 ml kg^{-1} h^{-1}).

On arrival in the induction room all patients were met by an anaesthetist other than the one who would be in charge of induction and monitoring of anaesthesia. Having confirmed their hydration status clinically, and noted the duration of fasting from oral fluids together with preoperative Na^+ and urea values, a 16-French gauge peripheral cannula was inserted. Patients were allocated randomly, using a sealed, sequentially numbered, envelope technique, to one of two groups: group HS received 6% hetastarch 500 ml (Hespan) followed by crystalloid (Hartmann's solution) 500 ml over 10–15 min while the patient was positioned and prepared for spinal anaesthesia; group MX received methoxamine 10 mg by deep gluteal i.m. injection after being positioned for spinal anaesthesia. Maintenance fluid (1.5 ml kg^{-1} h^{-1}) using crystalloid (Hartmann's solution) was infused continuously in all patients.

Spinal anaesthesia was induced in all cases in the lateral position, the operative side inferior, at L2–3 or L3–4, using 0.5% hyperbaric bupivacaine 2.25–3.0 ml (Marcain; Astra Pharmaceuticals), with a 22-gauge spinal needle, injected over 15–20 s under aseptic conditions by an anaesthetist other than the one who had administered the preventive strategies described above and who was therefore unaware of the study groups. This physician also managed the patient during anaesthesia and noted the haemodynamic data. The volume of bupivacaine used was left to this anaesthetist, depending on the patient's weight, height, sex and physical condition. Patients were kept in the lateral position for another 5 min to ensure they were pain free before transfer to the position for surgery. Sensory level was determined bilaterally at 15 min using pinprick.

Systolic (SAP), mean (MAP) and diastolic (DAP) arterial pressures were measured by automated, non-invasive oscillotonometry (Dinamap, Datex Cardiocap II, Helsinki, Finland) on three successive occasions on arrival in the induction room to establish baseline levels, at 2-min intervals until 30 min after induction of spinal anaesthesia and at 5-min intervals thereafter. Heart rate (HR) was noted from continuous electrocardiography, and pulse oximetry was also monitored throughout spinal anaesthesia and surgery. Hypotension was defined as a 25% decrease from baseline for both SAP and MAP, or an absolute systolic value <100 mm Hg. Rescue therapy for hypotension comprised methoxamine 2–4 mg i.v., repeated at 2-min intervals as necessary. This was given if SAP was <100 mm Hg on two consecutive readings or if indicated on clinical grounds, that is if new pallor was noted or if the patient reported nausea, vomiting or unusual lightheadedness. Blood loss was estimated in the perioperative period by the sum of collected spilt blood and swab weighing. Observations were discontinued after 70 min or immediately after arrival in the recovery room, whichever occurred sooner.

Data were analysed using Statsview II. Mean (95% confidence intervals) values were obtained for normally distributed data and compared using the Student's unpaired *t* test. Repeated measures analysis of variance was used for serial measures of SAP, MAP and HR. Paired Student's *t* test and *post hoc* Bonferroni correction for multiple comparisons were used for comparison of these variables between baseline and sequential times. The Mann–Whitney *U* test was used to compare skewed data. Categorical data were compared with chi-square analysis of contingency tables with Yates' correction or Fisher's exact test where cell values were <5. The power of this study was calculated prospectively as follows: in a previous investigation, we found an incidence of spinal-induced hypotension in the elderly of 50%,[11] consistent with other studies. The minimum clinically

important difference we wished to detect was a 30% difference in the proportion of patients developing hypotension (e.g. 65% *vs* 35%), assuming equal patient groups. Thus this study had 75% power to detect these differences at P = 0.05 and n = 30 in each group.

Results

Although 65 patients were enrolled in the study, two (one in each group) were subsequently lost because of failure to establish spinal anaesthesia, and another (group MX) had inadequate subarachnoid block, all three requiring general anaesthesia. Hence, data from 62 patients were analysed; n = 32 in group HS and n = 30 in group MX.

The groups were similar in age, sex, characteristics, preoperative Na^+ and urea values, and preoperative fasting time. Blood loss was not significantly different between groups (table 1). Median time to induction of spinal anaesthesia after commencement of therapy (volume administration or methoxamine i.m.) was 10.2 (range 8–13) min. Sensory level at 15 min and proportion of patients with a high block (defined as T8 or higher) were also similar in each group, and the overall proportion of patients with a high block was 53%. Mean time to onset of hypotension was 17.2 min in group HS and 20.7 min in group MX (ns) (table 1).

The incidence of SAP hypotension was 75% in group HS compared with 47% in group MX (P = 0.03, odds ratio (OR) = 3.43; 95% confidence interval (CI) for this 28% difference in the proportion of patients developing SAP hypotension was 4.7–51.3%). Similarly, 67% of patients in group HS compared with 47% in group MX demonstrated MAP hypotension (P = 0.09, OR = 2.51). The incidence of rescue methoxamine therapy was 38.5% (53% for group HS *vs* 27% for group MX; P = 0.04, OR = 3.11). However, in those patients given methoxamine, the mean dose was not significantly different between groups (8.9 (95% CI 5.6–12.2) *vs* 6.3 (3.0–9.6) mg) (table 2).

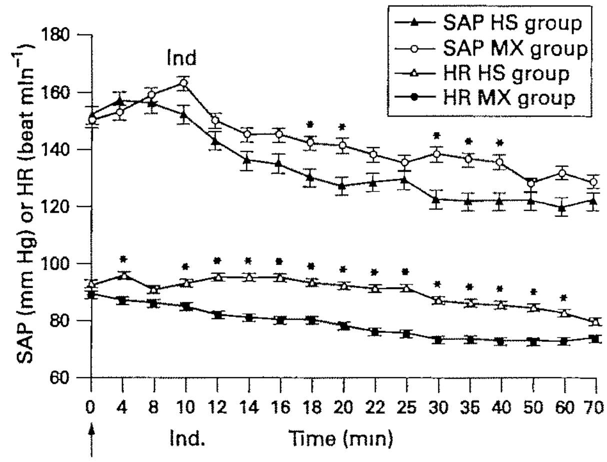

Figure 1 Mean (SEM) systolic arterial pressure (SAP) and heart rate (HR) in groups HS and MX. Ind. = Induction of spinal anaesthesia; arrow indicates time of volume administration or administration of methoxamine i.m. $*P < 0.05$.

Absolute SAP and MAP increased in both groups after commencement of therapy and before spinal anaesthesia, but the difference between groups was not significant (fig.1). HR remained unchanged in group HS but decreased significantly from baseline in group MX and remained significantly lower in group MX than in group HS at all times (fig. 1). After induction of spinal anaesthesia, SAP and MAP decreased significantly in each group with respect to baseline, but absolute values of SAP and MAP were consistently higher in group MX up to 60 min after induction of spinal anaesthesia, reaching statistical significance at the times shown (figs 1, 2). Diastolic arterial pressure in groups HS and MX were: baseline 81.3 (95% CI 75–86) *vs* 79.2 (73–85) mm Hg, at 8 minutes after methoxamine or volume administration 67 (61–73) *vs* 75 (71–80) mm Hg (P < 0.05) and at 20 min after induction of spinal anaesthesia, 64 (59–70) *vs* 71 (65–79) mm Hg (P < 0.05). There were no significant differences between groups in diastolic arterial pressure at any other time.

Discussion

Spinal anaesthesia blocks efferent sympathetic fibres and reduces systemic vascular resistance by decreasing the sympathetic tone of the arterial circulation. There is also peripheral venous pooling of blood, which may reduce cardiac output.[5 19] Such changes frequently cause systemic hypotension, which may be harmful in the elderly with incipient cardiac and renal failure. However, baroreceptor-mediated compensatory cardiovascular responses result which tend to maintain arterial pressure.[19] Should the sensory level extend to T8, release of catecholamines by the

adrenal gland is compromised and if it reaches T1, all cardiac compensation potential is lost.[5]

Our comparison of two measures intended to reduce hypotension in elderly patients showed greater haemodynamic stability with pre-emptive methoxamine 10 mg i.m. given 10 min before spinal anaesthesia compared with an infusion of 6% hetastarch and crystalloid, in contrast with recent studies in parturients[11 12] and in non-pregnant young women, which found fluid administration of apparent benefit.[23] This may reflect the fact that we used a total volume of 1 litre (6% hetastarch 500 ml and crystalloid 500 ml) compared with 1.5 litre[13 20] and 2 litre.[12] Elderly patients with hip fractures are particularly susceptible to hypotension during spinal anaesthesia because they may be hypovolaemic from blood loss into the fractured joint and have a high incidence of co-existing disease. However, we believe that rapid infusion of up to 2 litre of fluid would possibly result in haemodynamic embarrassment from circulatory overload.

We propose that colloid solution would be more effective in preventing spinal-induced hypotension, as its large molecular weight ensures it remains in the plasma body fluid compartment. None the less, a recent study with large numbers of patients ($n = 85$) comparing crystalloid, gelatin colloid and no fluid treatment in patients aged more than 60 yr found no significant difference in the incidence of hypotension or requirements for rescue vasopressor therapy.[13] Intravascular fluids *per se* do not reverse decreases in systemic vascular resistance, rather they may increase cardiac output.[3 5 21] A more plausible explanation for the failure of this combined fluid administration regimen in the elderly may be that the reduced physiological reserve of older patients may make them less able to respond to volume with a corresponding increase in cardiac output.[3 17] Moreover, 75% of any crystalloid infused rapidly diffuses into the interstitium, where it cannot be as effective as a volume expander.[22] Furthermore, infused fluid (with either crystalloid alone or in combination with hetastarch) stimulates atrial natriuretic peptide (ANP) secretion in women undergoing spinal anaesthesia for Caesarean section,[23] tending to decrease systemic vascular resistance and initiate diuresis. If this were also true in elderly patients, it may explain the ineffectiveness of fluid administration in preventing hypotension.

Ephedrine, a combined alpha and beta agonist, is the most commonly used vasopressor in the elderly.[3] It may be ineffective in reversing the spinal-induced decrease in SVR, possibly because of its beta effect, causing arteriolar vasodilatation in opposition to its alpha vasoconstrictive effect.[16 17] Moreover, its beta-mediated increase in heart rate exposes elderly patients with latent coronary artery disease to myocardial ischaemia. However, in ASA III patients, many of whom would be in the elderly age range, a combination of prophylactic i.m. and i.v. ephedrine improved haemodynamic stability, albeit with tachycardia.[24 25] In contrast, a pure alpha adrenergic agonist (metaraminol), given as a continuous infusion (0.5–5.0 mg h^{-1}), maintained SAP by increasing SVR and central venous pressure, compared with a similar group of elderly patients receiving synthetic colloid alone. However, one-third of patients receiving the metaraminol infusion developed inadvertent hypertension.[18] The increased SVR was associated with a decrease in heart rate both in this and our present study, presumably because of a baroreceptor-mediated reflex bradycardia. Despite the fact that we did not find inadvertent hypertension after methoxamine, it could be that a prolonged delay or failure to establish spinal anaesthesia would cause inadvertent hypertension.

Our finding of improved haemodynamic stability with methoxamine is the first report of its efficacy in male and female elderly patients undergoing spinal anaesthesia for emergency orthopaedic surgery, and is consistent with the results of another small study ($n = 36$) in which MAP was maintained and blood loss reduced in males undergoing transurethral resection of the prostate, given methoxamine 10 mg i.m., 15 min before induction of spinal anaesthesia.[26] In our study, there was no significant difference in blood loss between those receiving methoxamine and those receiving fluid administration. We chose to study methoxamine i.m. believing this to be a more convenient form of administration and less expensive because an infusion pump is not required. Although we have shown that arterial pressures were better preserved using pre-emptive methoxamine, its effect on cerebral and coronary perfusion remains unknown. Such measurements are beyond the scope of this study and are not widely available in current clinical practice.

Our data may have been adversely affected by some of the design features of this study. Baseline arterial pressure was calculated from the mean of three readings, obtained in the semi-recumbent position immediately on arrival in the induction room when many patients would be quite anxious. Subsequently, readings were obtained in the supine or lateral position of surgery. Non-invasive (Dinamap) recording of arterial pressure is accurate only to within ±10%, but the same machine was used in all patients and invasive arterial pressure measurements are rarely used in our practice in this setting. The fasting time varied from 10 to 15 h but all patients were given i.v. fluids at maintenance rates during this time. It was not practical for one anaesthetist to perform all spinal blocks, thus some variation in technique may have occurred. Sensory level was assessed at 15 min, which may have been too early, even using a hyperbaric solution. It would have been interesting to re-assess sensory level and to continue our observations for another 30–60 min in the recovery room to confirm that haemodynamic values were beginning to stabilize.

There is widespread consensus that normovolaemia must be maintained during spinal anaesthesia, and crystalloid 8 ml kg^{-1} has been suggested by Critchley as an appropriate infusion volume to be given as the block is evolving, that is over the initial 10–20 min. However, use of large pre-emptive infusions over a shorter time span are demonstrably ineffective in preventing spinal-induced hypotension and may be detrimental, especially in the elderly.[3, 5, 11–13, 16–19, 27]

In summary, in this prospective, randomized, double-blind, clinical study, methoxamine 10 mg i.m., given 10 min before spinal anaesthesia, resulted in greater haemodynamic stability in normovolaemic elderly patients undergoing emergency hip surgery compared with i.v. administration of 6% hetastarch 500 ml and crystalloid solution 500 ml. The previously reported benefit of this fluid regimen may not extend to the elderly.

LABORATORY INVESTIGATIONS

Reduced quality of clot formation with gelatin-based plasma substitutes

S. N. Mardel, F. M. Saunders, H. Allen, G. Menezes, C. M. Edwards, L. Ollerenshaw, D. Baddeley, A. Kennedy and R. M. Ibbotson

Summary

We have studied, over a wide range of dilutions using techniques of clot weight, thrombelastography and scanning electron microscopy, the physical properties of a blood clot formed *in vitro* when fresh blood was diluted with gelatin-based colloid solutions compared with crystalloid controls. The colloid solutions tested (3.5% polygeline (Haemaccel) and 4% succinylated gelatin (Gelofusine)) produced clots that had reduced median weight ($P<0.001$ and $P=0.018$, respectively) and reduced mean shear modulus ($P<0.001$) compared with crystalloid controls. Scanning electron microscopy showed that the fibrin formed a less extensive mesh in the presence of the gelatin-based colloids compared with crystalloid. Reduction in clot quality with gelatin-based colloids has not been noted previously and further work is needed to ascertain if this occurs *in vivo* as these solutions are used frequently in patients who require full haemostatic competence. (*Br. J. Anaesth.* 1998; **80**: 204–207)

Keywords: blood, coagulation; blood, colloids; fluids, i.v.; blood, haemostasis; blood, replacement; measurement techniques, thrombelastography

Plasma substitutes containing degraded and modified gelatin are being used increasingly in pre-hospital, resuscitation, perioperative and intensive care situations. Often they are the fluid of choice in patients with uncontrolled haemorrhage both before blood transfusion and in conjunction with transfusion of packed cells. Unlike the dextran and starch solutions, so far they have been considered as having no significant effect on clotting mechanisms following studies based principally on clotting times.[1–4]

While measuring whole blood coagulation times after *in vitro* dilution with colloids we noted a striking difference in clot quality compared with that seen with dilution using crystalloid. Our preliminary findings have been reported previously.[5] In this article we describe more detailed investigations using clot weights, haematological analysis, thrombelastography and scanning electron microscopy, and include a description of the dose–response effect of varying degrees of dilution using regression analysis.

Materials and methods

Wherever fresh whole blood was used, care was taken to avoid prolonged venous stasis, venepuncture from the same site or delays in pipetting, and experiments were conducted under strict temperature control.

CLOT WEIGHTS

A total of 35 fresh whole blood samples were diluted to 15%, 30%, 45%, 60% and 75% with 0.9% sodium chloride and Ringer's solution (controls) or the test substances, 4% succinylated gelatin (Gelofusine, B. Braun (Medical) Ltd) and 3.5% polygeline solution (Haemaccel, Hoescht UK Ltd). After dividing each sample into test and control, the total volume of each sample after dilution was 5 ml. Clot weights were measured using the method described by Macfarlane.[6] Because the clots would not adhere to a glass rod the test was modified by separating the clot from plasma on gauze in a funnel. Clots were weighed on an electronic balance and then examined physically, both by inspection and by attempted dissection with a blunt probe. The remaining serum was then subjected to the following analyses: red blood cell count, platelet count, fibrinogen (Clauss technique) and D-dimers (Dimertest II, Agen Biomedical Ltd).

THROMBELASTOGRAPHY

Coagulation of 70 samples of fresh whole blood at the same dilutions as above were examined by thrombelastography. Each sample was similarly divided and diluted using the test and control solutions and the paired samples placed into the test cylinders of a thrombelastograph (Hellige GMBH) using the method described by De Nicola.[7] This measures the elasticity of the fibrin network within a clot and records this on a calibrated paper chart. Measurements are not affected by viscosity changes. Maximum amplitude (MA) of the graph is measured in millimetres and from this shear modulus (ε) is calculated using the formula $\varepsilon=(100\times MA)/(100-MA)$,

given that the normal value of MA is 50 mm for whole blood, and this corresponds to a modulus of 100.

SCANNING ELECTRON MICROSCOPY

Clots were examined by scanning electron microscopy (SEM) using fresh whole blood diluted to 33% and 66% with 0.9% sodium chloride (control), 3.5% polygeline and 4% succinylated gelatin. An additional control of undiluted blood was also examined. Blood clots were fixed initially with 2.5% glutaraldehyde, buffered with sodium cacodylate 0.1 mol litre^{-1} (pH 7.4) containing $CaCl_2$ 2 mmol litre^{-1} for 2 h, then washed in the same buffer and post-fixed in osmium tetroxide for 1 h. The clots were washed, dissected into smaller pieces in 70% ethanol and stored in the same solution overnight at 4°C. The clots were then dehydrated, critical point dried and sputter-coated with gold.[8] All SEM specimens were examined in a Hitachi S-4500 field emission scanning electron microscope, using an accelerating voltage of 5 kV.

Comparison of differences in weight between the plasma substitutes and their controls was carried out using a Wilcoxon signed rank test; elasticity was compared using paired *t* tests. To investigate the relationship between dilution and elasticity, regression techniques were used. Both linear and quadratic models were fitted to the data to assess the observed relationship.

Results

None of the whole blood dilutions containing gelatin colloids formed a firm plug compared with those containing crystalloid. This simple observation occurred regardless of the strength of dilution, and on blunt dissection the controls showed better elastic properties. Examination of the remaining serum was negative for fibrinogen and cross-linked fibrin degradation products in both test samples and controls, and there was no difference in full blood count analysis (haemoglobin concentration, red blood cell count and platelet count). Examination of the clots by light microscopy was also similar. There was no difference in clot weights or thrombelastograms between the 0.9% sodium chloride and Ringer's solution controls.

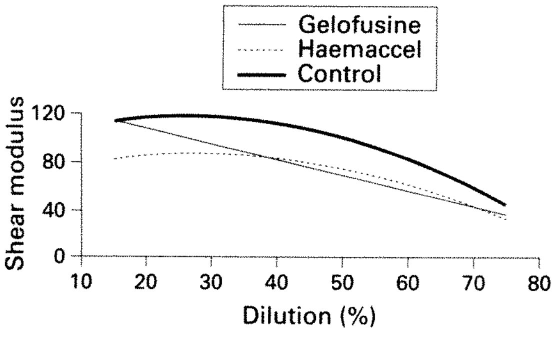

Figure 1 Dose–response curves showing reduction in clot strength (shear modulus) for increasing dilution of fresh blood with the different fluids. Curves were drawn using the best fit from regression analyses (marked † in table 3).

CLOT WEIGHTS

Median clot weights were considerably lower for both plasma substitutes compared with the control solutions (table 1). Median clot weight for Haemaccel was 15.6% lower than that for its control; this value was 25.9% for Gelofusine. These results were significant for Haemaccel and control solutions ($P<0.001$, $z=-3.81$), and Gelofusine and control solutions ($P=0.018$, $z=3.12$).

THROMBELASTOGRAPHY

The elasticity of the plasma substitutes was also considerably lower than that of their controls (table 2). Mean elasticity of the Haemaccel samples was 26.2% lower than that of their controls, and Gelofusine was 22.2% lower. There were significant differences in mean clot strength for both Haemaccel ($P<0.001$, $t=-11.9$) and Gelofusine ($P<0.001$, $t=-7.92$) compared with controls.

The relationship between solutions and dilution levels is plotted in figure 1. The regression models are summarized in table 3. The Haemaccel data showed a quadratic relationship with dilution. By adding the dilution^2 term to the linear model, a significantly greater amount of variation was explained. Gelofusine had a linear relationship with dilution, but in this case the dilution^2 term did not explain enough variation to be added to the equation. The model with the dilution term alone, however, explained 77.1% of the variation observed in the Gelofusine shear modulus. The relationship between saline controls and dilution was similar to that of Haemaccel, but with the higher levels of elasticity observed above.

SCANNING ELECTRON MICROSCOPY

The widespread mesh pattern of fibrin strands seen in the undiluted whole blood control was retained in the 0.9% sodium chloride controls at both dilutions. This reticular network was reduced considerably in

Table 3 Regression models showing possible relationships between clot strength and dilution for individual fluids (mean (SEM)). †Regression analyses producing the best fit

clots containing gelatin-based solutions at 66% dilution (see figs 2–5). The fibrin strands appeared often to be thinner in the test solutions at higher magnification but there was more variation.

Discussion

Gelatin-based plasma substitutes are being used increasingly in the pre-hospital situation and in hospitalized patients requiring massive transfusion. In this situation they may sometimes be the only infusion fluid given together with concentrated red cells, thus producing high concentrations *in vivo.* Some clinicians have an impression that patients resuscitated with gelatin-based colloids develop a tendency to bleed more than those resuscitated with crystalloid, although a search of the literature shows no studies to confirm this. Any increase in bleeding could be a result of either an increase in arterial pressure and perfusion (both of which are clearly easier to achieve with resuscitation using a colloid) or a disturbance in the clotting mechanism. The latter could be because of dilutional and wash-out effects (again reflecting their improved retention in the normal circulation compared with crystalloid) or to interference with the normal coagulation process.

Other colloids used initially in the resuscitation of haemorrhage were found later to interfere with the coagulation process: these include dextran[9] and the hydroxyethyl starches.[10] These effects, principally on factor VIII and platelet adhesion, were detectable using more conventional tests involving measurement of various clotting times. Some workers have reported inhibition of platelet activity by polygeline[11] which is not considered to have a significant effect on coagulation.

One recent study found no significant change in clot strength with Haemaccel but examined only 20% dilution.[12] Another study examining the effects of varying haemodilution on clot strength used proteinaceous solutions and did not include any gelatin-based plasma substitutes.[13] In contrast with our study, they found that these solutions (including albumin) caused a general increase in clot strength compared with saline controls. However, their control dilutions with saline at 25%, 50% and 75% caused a comparable decrease in clot strength to the controls in our study, and furthermore they found similar results when comparing their results *in vitro* with *in vivo* work in rats.

We have shown that *in vitro,* these gelatin-based colloidal solutions reduced the weight of clots while still consuming all of the fibrinogen and trapping similar amounts of red cells and platelets. Therefore, the alteration in clot quality appears to reflect a change in organization of the clot and this is supported by the reduction in elasticity seen macroscopically, when measured with the thrombelastograph and with the arrangement of the fibrin seen on SEM.

Fibronectin is a glycoprotein which forms covalent cross linkages and non-covalent associations with fibrin. These bonds aid the determination of clot architecture and mechanics.[14] Denatured collagen (gelatin) has been shown to bind with fibronectin[15] and polygeline infusion has been shown to decrease plasma fibronectin concentrations *in vivo.*[16] These gelatin-based products may become incorporated into developing clots, thus interfering with polymerization of fibrin monomers and growth of the macromolecular structure of the clot.

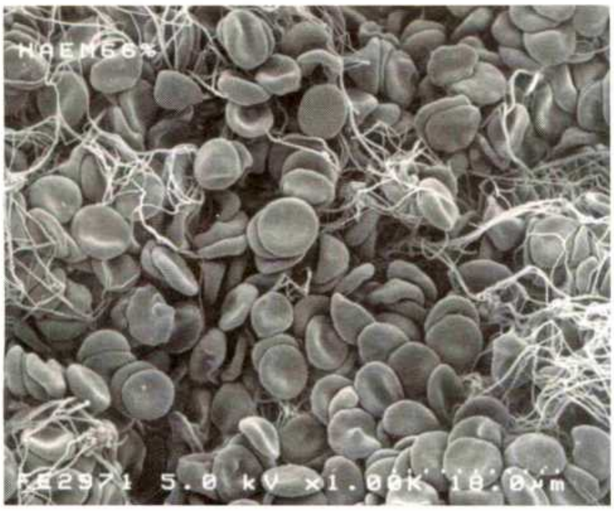

Figure 4 Scanning electron micrograph of whole blood diluted to 66% with polygeline (Haemaccel).

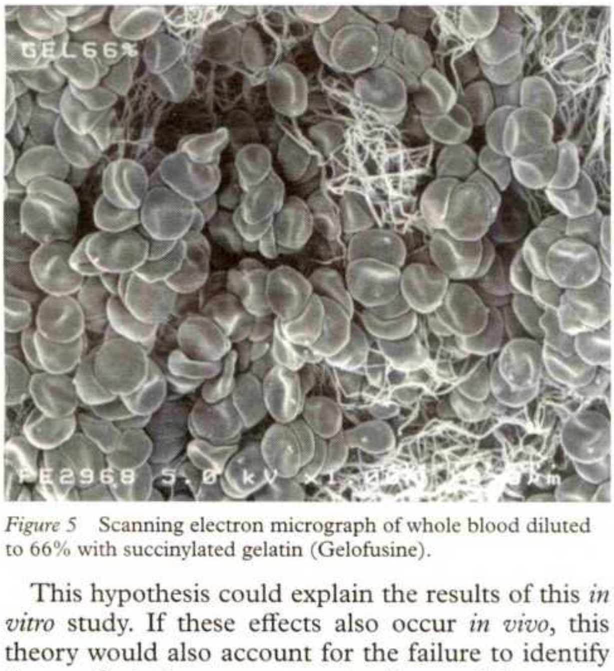

Figure 5 Scanning electron micrograph of whole blood diluted to 66% with succinylated gelatin (Gelofusine).

This hypothesis could explain the results of this *in vitro* study. If these effects also occur *in vivo*, this theory would also account for the failure to identify these effects by measurement of normal haematological variables (such as aPTT and PT tests) which use fibrin formation as an end-point and ignore subsequent events critical to the formation of a viable clot and may not guarantee their safety in situations involving severe or uncontrolled haemorrhage. Any reduction in quality of clot formation would be especially harmful in the pre-hospital situation, where a new clot is being formed, and in patients requiring full haemostatic competence. Studies are needed to explain the mechanism for these observed *in vitro* effects and to determine if they occur *in vivo*.

Endocrine and metabolic effects of hypotension or halothane inhalation in sheep anaesthetized with pentobarbital

P. M TAYLOR

Summary

We have studied the mechanism whereby halothane induces adrenocortical activity in eight sheep anaesthetized twice for 2 h with pentobarbital. During the second hour they received infusion of nitroprusside to lower mean arterial pressure by 40 mm Hg (group NP) or on another occasion they inhaled 0.5% halothane (group HAL). Plasma concentrations of cortisol, adrenocorticotrophic hormone (ACTH), arginine vasopressin (AVP), glucose and lactate were measured. Infusion of nitroprusside increased cortisol concentrations from mean 44 (SD 33) to 256 (131) nmol litre^{-1} ($P < 0.05$), AVP from 19 (14) to 174 (102) pmol litre^{-1} ($P < 0.05$) and ACTH from 30 (17) to 54 (32) pmol litre^{-1}. Glucose and lactate concentrations did not change significantly. After 60 min of halothane administration, there were fewer effects: plasma cortisol increased from 47 (39) to 63 (44) nmol litre^{-1} ($P > 0.05$) and AVP from 14 (11) to 32 (29) pmol litre^{-1} ($P > 0.05$) while ACTH decreased from 32 (13) to 25 (10) pmol litre^{-1}. The AUC_{60-120} values for all three hormones were significantly lower in group HAL than in group NP ($P < 0.01$). Glucose was unchanged but lactate concentration decreased. These results support, but do not prove, the hypothesis that hypotension is the main stimulus to pituitary–adrenocortical activity during halothane anaesthesia in sheep. A direct effect of nitroprusside cannot be ruled out. (*Br. J. Anaesth.* 1998; **80**: 208–212)

Keywords: anaesthetic techniques, hypotensive; hypnotics barbituate, pentobarbital; anaesthetics volatile, halothane; hormones, adrenal; metabolism, endocrine; sheep

It has long been recognized that noxious stimuli induce an endocrine stress response in mammals, manifested as increased pituitary–adrenocortical (PAC) activity leading to an increase in circulating cortisol.[1] It is also well known that surgery causes a stress response but anaesthesia itself is generally considered to be relatively benign.[2] Taylor[3 4] reported that horses had a marked adrenocortical response to volatile agent anaesthesia which is not seen during i.v. anaesthesia with either propofol, barbiturates, detomidine–ketamine or climazolam–ketamine.[5–8] Sheep have been found to respond to halothane and barbiturate anaesthesia in a manner similar to that of horses[9] and the question arises as to whether or not volatile anaesthesia acts as a noxious stimulus in most species. It is conceivable that in humans, rigorous attention to maintenance of fluid balance and cardiovascular homeostasis during anaesthesia may prevent a stress response from occurring. In addition, as there are few studies in humans where anaesthesia has been investigated in the absence of surgery,[10 11] any effects caused solely by anaesthesia may have been obscured.

It seems likely that some aspect of volatile agent anaesthesia acts as a noxious stimulus inducing a stress response, at least in horses and sheep. It is possible that hypotension and its related effects on perfusion may be responsible. Certainly, haemorrhage is known to cause or enhance adrenocortical activity.[12] However, it is possible that volatile agents may induce an endocrine response by some other unidentified mechanism.

In this study, designed to investigate what stimulates PAC activity during halothane anaesthesia in sheep, an attempt was made to differentiate hypotension from a putative specific effect of halothane. The effects of halothane-free (nitroprusside-induced) hypotension or hypotension-free (sub-anaesthetic doses) halothane exposure were investigated during barbiturate anaesthesia. Pentobarbital was chosen as this does not induce adrenocortical activity.

Materials and methods

ANIMALS

We used eight non-pregnant Welsh Mountain ewes, aged 2–3 yr, weighing 27–39 kg (mean 33 kg) and the study was conducted under Home Office licence PPL 80/83. They were housed indoors with free access to hay and water, except during the 18 h before anaesthesia when they were allowed only water. Each ewe was investigated in two studies, with at least 1 week between anaesthetics. The ewes were prepared for monitoring by surgical exteriorization of the carotid artery into a skin loop at least 2 weeks before the experiment ($n = 2$) or by placement of an indwelling polytetrafluoroethylene catheter in the aorta via the femoral artery at least 3 days before the experiment ($n=6$).[13] Preparatory surgery was performed under halothane anaesthesia. For each experiment, a 14-SWG catheter was inserted in the jugular vein and, when appropriate, a 20-SWG catheter was inserted in the relocated carotid artery approximately 30 min before induction of anaesthesia.

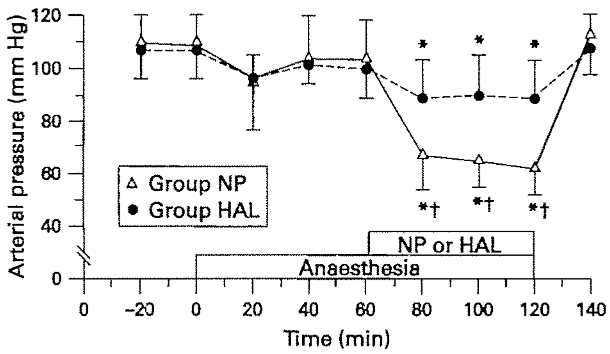

Figure 1 Mean (SD) arterial pressure in eight sheep during pentobarbital anaesthesia. Group NP: nitroprusside-induced hypotension between 60 and 120 min; group HAL: 0.5% inspired halothane between 60 and 120 min. Anaesthesia was induced at 0 min. Pentobarbital infusion was stopped at 120 min. $^*P < 0.05$ compared with control; $^\dagger P < 0.05$ compared with 60-min value. AUC_{60-120} was significantly different between groups ($P < 0.05$).

ANAESTHESIA

Anaesthesia was induced, without premedication, with pentobarbital 16–29 (mean 22) mg kg^{-1} i.v. and the trachea intubated with a cuffed tracheal tube. Anaesthesia was maintained for 2 h with pentobarbital 0.2–0.3 mg kg^{-1} min^{-1} as required, given by incremental doses at 5-min intervals or by infusion (Harvard syringe pump), resulting in a total maintenance dose of 16–39 (mean 31) mg kg^{-1}. The sheep breathed spontaneously throughout anaesthesia and oxygen was supplied either from a circle breathing system or via a T-piece. After 2 h of anaesthesia the sheep were allowed to recover breathing air; the tracheal tube was removed when the swallowing reflex returned.

During the second hour of anaesthesia, sodium nitroprusside was infused to produce hypotension, approximately 40 mm Hg below control values (group NP). A total dose of nitroprusside 405 (162) µg kg^{-1} was given. On another occasion, during the second hour of anaesthesia, the sheep breathed 0.5% (inspired) halothane in oxygen from a T-piece with fresh gas flow rates sufficient to prevent any rebreathing (group HAL). Four of the sheep received nitroprusside first and halothane second. The other four received halothane first and then nitroprusside.

MEASUREMENTS

The femoral or carotid artery catheter was used to record arterial pressure (Lectromed equipment) and for withdrawal of blood samples for pH and arterial blood-gas measurements (Radiometer 130). Heart rate was obtained from the pressure trace and ventilatory frequency by observation of the chest wall. Venous blood samples (5 ml) were obtained for endocrine and metabolite assays. Blood was divided between tubes containing EDTA and heparin and centrifuged immediately at 4 °C; plasma was harvested, frozen and stored at −20 °C until hormone and metabolite assay.

Control measurements were made approximately 20 min after the catheters had been inserted, when the sheep had been standing quietly under minimal restraint in sight of another ewe. A continuous arterial pressure trace was recorded for at least 10 min before any other measurements were made and blood samples obtained. During anaesthesia, sampling took place at 20-min intervals; another sample was obtained 20 min after the end of anaesthesia.

Depth of anaesthesia was monitored by normal clinical assessment, and the same range of pentobarbital infusion rates was used in both groups. The total dose of pentobarbital was 55 (6) mg kg^{-1} in group NP and 53 (4) mg kg^{-1} in group HAL ($P > 0.05$). Time to standing was recorded in minutes from the end of the 2-h anaesthetic period when the animals started to breathe air.

BIOCHEMISTRY

Plasma concentrations of cortisol, adrenocorticotrophic hormone (ACTH) and arginine vasopressin (AVP) were measured using radioimmunoassay (RIA).[14 15] Intra- and inter-assay coefficients of variation were, respectively, for cortisol 5.6% and 11.8%, for ACTH 8.1% and 16.4% and for AVP 16.8% and 21.5%. Plasma glucose and lactate concentrations were measured using standard colorimetric techniques modified for use on an automatic analyser.

STATISTICAL ANALYSIS

Results are given as mean (SD) unless stated otherwise. Changes with time within any study were analysed using analysis of variance (ANOVA) for repeated measures, followed by Dunnett's test to examine deviation from control or 60-min values (as indicated) in each anaesthetic study. Differences between groups were analysed by Student's unpaired *t* test of the area under the time curve taken from control to 20 min after anaesthesia (AUC_{0-140}) and from 60 to 120 min of anaesthesia (AUC_{60-120}).[16] Data that were not normally distributed were subjected to log transformation before analysis. $P < 0.05$ was considered significant.

Results

GROUP NP

Mean arterial pressure (MAP) did not change from control values during the first hour of anaesthesia but during infusion of nitroprusside it decreased significantly ($P < 0.05$) from the 60-min level to mean values of 63–68 mm Hg (fig. 1). MAP returned to control values within 20 min of ceasing nitroprusside and pentobarbital administration. Arterial oxygen tension (Pa_{O_2}) increased ($P < 0.05$) while the sheep inspired a high oxygen fraction; arterial carbon dioxide tension (Pa_{CO_2}) also increased ($P < 0.05$) and pH decreased ($P < 0.05$) (table 1). Heart rate and ventilatory frequency did not change significantly (table 1).

Plasma concentrations of cortisol (fig. 2), ACTH (fig. 3) and AVP (fig. 4) did not change significantly during the first hour of anaesthesia but all increased above the 60 min value thereafter ($P < 0.05$). Glucose and lactate concentrations did not change significantly throughout anaesthesia (table 1).

All sheep in group NP recovered normally and were standing, eating hay within 120 min after the end of anaesthesia.

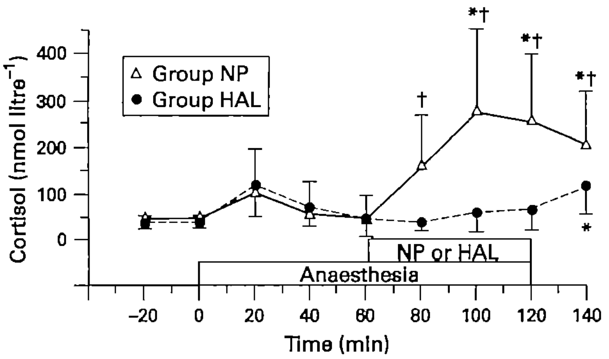

Figure 2 Mean (SD) plasma concentrations of cortisol in eight sheep during pentobarbital anaesthesia. Group NP: nitroprusside-induced hypotension between 60 and 120 min; group HAL: 0.5% inspired halothane between 60 and 120 min. Anaesthesia was induced at 0 min. Pentobarbital infusion was stopped at 120 min. $^*P < 0.05$ compared with control; $^†P < 0.05$ compared with 60-min value. AUC_{60-120} was significantly different between groups ($P < 0.01$).

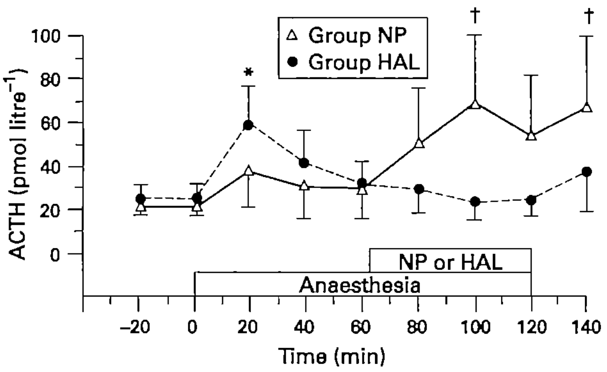

Figure 3 Mean (SD) plasma concentrations of adrenocorticotrophic hormone (ACTH) in eight sheep during pentobarbital anaesthesia. Group NP: nitroprusside-induced hypotension between 60 and 120 min, group HAL: 0.5% inspired halothane between 60 and 120 min. Anaesthesia was induced at 0 min. Pentobarbital infusion was stopped at 120 min. $^*P < 0.05$ compared with control; $^†P < 0.05$ compared with 60-min value. AUC_{60-120} was significantly different between groups ($P < 0.05$).

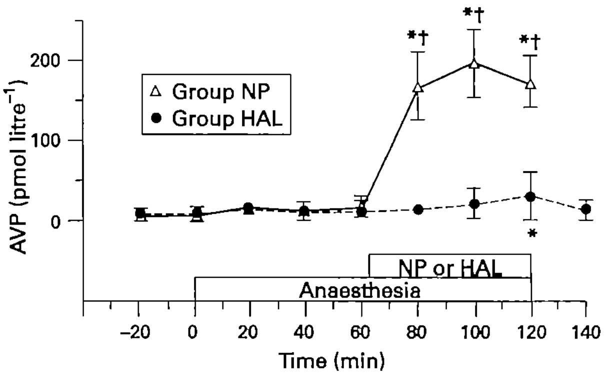

Figure 4 Mean (SD) plasma concentrations of arginine vasopressin (AVP) in eight sheep during pentobarbital anaesthesia. Group NP: nitroprusside-induced hypotension between 60 and 120 min; group HAL: 0.5% inspired halothane between 60 and 120 min. Anaesthesia was induced at 0 min. Pentobarbital infusion was stopped at 120 min. $^*P < 0.05$ compared with control; $^†P < 0.05$ compared with 60-min value. AUC_{60-120} was significantly different between groups ($P < 0.01$).

GROUP HAL

MAP changed little from control values during the first hour of anaesthesia but decreased below control values during halothane administration to mean values of 89–90 mm Hg ($P < 0.05$) (fig. 1). The values recorded during halothane inhalation were not significantly lower than the 60-min value ($P > 0.05$). MAP–AUC_{60-120} was significantly higher than that recorded in group NP ($P < 0.05$). MAP returned to control values within 20 min of ceasing halothane administration. Pa_{O_2} and Pa_{CO_2} increased ($P < 0.05$) during anaesthesia and pH decreased ($P < 0.05$) (table 1). Heart rate did not change significantly (table 1) and ventilatory frequency decreased only transiently at 20 min. There were no significant differences in arterial blood-gas tensions, heart rate or ventilatory frequency between groups HAL and NP.

There were no significant changes in plasma concentrations of cortisol (fig. 2), ACTH (fig. 3) or AVP (fig. 4) during halothane administration and AUC_{60-120} for all three hormones was significantly lower than that recorded in group NP ($P < 0.01$). Glucose concentration did not change but lactate decreased after 60 min, reaching mean values of 0.6 mmol litre^{-1} at 120 min ($P < 0.05$) (table 1). There were no significant differences in glucose or lactate concentrations between groups NP and HAL.

Table 1 Mean (SD) arterial oxygen partial pressure (Pa_{O_2}), arterial carbon dioxide partial pressure (Pa_{CO_2}), pH, heart rate, and plasma glucose and lactate concentrations during pentobarbital anaesthesia in eight sheep with nitroprusside-induced hypotension (group NP) or 0.5% inspired halothane (group HAL). Anaesthesia was induced at 0 min. Pentobarbital infusion was stopped at 120 min Halothane or nitroprusside was given from 60 to 120 min. $^*P<0.05$ compared with control. No significant differences between groups

Discussion

We have found that nitroprusside-induced hypotension during pentobarbital anaesthesia caused marked PAC activity in sheep; this supports the hypothesis that during halothane anaesthesia, adrenocortical activity is stimulated by hypotension. However, as it proved impossible to give low doses of halothane without causing slight hypotension, it is not clear if the slight PAC stimulation during halothane administration was caused by mild hypotension or by another effect of halothane. It is also impossible to exclude a direct effect of nitroprusside on PAC activity.

Increases in circulating ACTH, AVP and cortisol have been recognized for some time as integral components of the stress response, although the precise changes evoked depend on the nature of the stressor and the species involved.[17] It has long been known that haemorrhage is one such stressor and that it induces PAC activity through stimulation of afferent input from the baroreceptors.[12] Caraty and colleagues[18] demonstrated that haemorrhage in sheep caused an increase in corticotrophin releasing factor (CRF) and AVP concentrations in hypothalamic portal blood (HPB), with a consequent increase in peripheral concentrations of ACTH and cortisol. Unfortunately, they did not report the simultaneous effects on arterial pressure. Nitroprusside-induced hypotension was used by Keller-Wood and Wood[19] as a stressor in a study of PAC behaviour in conscious sheep; results indicated that hypotension alone induced marked PAC activity. The authors reported large increases in plasma ACTH in response to a slightly greater degree of hypotension than that reported in this article. It is conceivable that pentobarbital anaesthesia may blunt the response to hypotension, but the increases in ACTH, AVP and cortisol were substantial none the less. Most investigations into endocrine responses to induced hypotension in humans have been confined to sympathoadrenal activity and the renin–angiotensin–aldosterone axis.[20] [21] Newton and colleagues[22] studied a wider range of endocrine and metabolic responses to induced hypotension during anaesthesia for middle ear surgery and found that three hypotensive methods led only to a minimal endocrine response typical for "low stress" surgery.

AVP is released into the HPB in response to stress and acts as one stimulus to ACTH release.[17] However, it is also involved in cardiovascular homeostasis and is released into the peripheral circulation from the posterior pituitary in response to hypotension and increases in blood osmolarity.[23] AVP is also released in response to atrial firing when filling pressure is reduced.[24] In our study, the relative contribution of hypotension or decreased filling pressure to stimulation of AVP release was not addressed as filling pressures were not measured. The precise role of AVP as a component of the stress response is unclear; its release in response to hypotension can be regarded as a reflex response to maintain cardiovascular stability. However, AVP is also released in response to stimuli such as surgery where arterial pressure is not affected,[25] the amount released appearing to correlate with the degree of surgical stimulus.[26]

The influence of anaesthesia on AVP release is less clear. In a preliminary study, it was shown that some anaesthetics, including halothane, increased circulating AVP, while others such as pentobarbital had little effect. Simpson and Forsling[25] reported that patients anaesthetized with halothane during bypass surgery developed much higher circulating concentrations of AVP than those receiving nitrous oxide only. In contrast, Leighton, Lim and Wilson[27] showed that halothane anaesthesia does not always affect plasma AVP. There is no doubt that AVP is involved in arterial pressure control during anaesthesia, and is increased by hypotension.[28] However, it is likely that the relationship is complex and depends on fluid load and perfusion, not simply on arterial pressure.[29]

Although this study has not been able to confirm that adrenocortical activity induced during halothane anaesthesia is a result of its hypotensive effect, the data are consistent with the hypothesis. If this proves a correct assumption the question arises as to whether or not PAC activity results from hypotension-induced increases in baroreceptor afferent input or from a more fundamental effect associated with hypotension, such as reduced tissue perfusion. Increases in lactate are commonly reported as a component of the metabolic response to surgery[2] but may also relate to reduction in tissue perfusion and an increase in anaerobic metabolism.[30] Lactate decreased during the second hour of anaesthesia in group HAL but did not change in group NP. This suggests that tissue perfusion may have been worse during nitroprusside administration, presumably as a result of hypotension. Inadequate tissue perfusion may act as, or enhance, the stimulus to the stress response during anaesthesia.

In our study, only the inspired halothane concentration was measured as herbivores exhale a substantial amount of methane which affects the output of infrared anaesthetic agent monitors.[31] However, as no rebreathing took place and all sheep experienced similar rates of fresh gas flow, the amount of halothane received was sufficiently similar for the purposes of this study.

No attempt was made to measure cardiac output or any other index of tissue perfusion and there was no evidence that nitroprusside and halothane affected arterial pressure, and thus tissue perfusion, by the same mechanism. Future studies should be directed towards investigating the effect of halothane anaesthesia where normotension is maintained by fluid or inotrope infusion. Inclusion of measures of tissue perfusion would aid interpretation of the data.

Production of nitrogen dioxide in a delivery system for inhalation of nitric oxide: a new equation for calculation

L. Lindberg and G. Rydgren

Summary

We have evaluated the kinetics of nitrogen dioxide production in a system for inhalation of nitric oxide. In addition to a small fraction of contamination of nitrogen dioxide in the nitric oxide stock gas, a considerable part of the total concentration of nitrogen dioxide is formed immediately after mixing of nitric oxide and oxygen. This initial build-up of nitrogen dioxide is followed by a linear, time-dependent increase in the concentration of nitrogen dioxide. An equation describing the concentration of nitrogen dioxide in the delivery system is formulated: $[NO_2] = k_A \times [NO] + k_B \times [NO]^2 \times [O_2] + k_C \times t \times [NO]^2 \times [O_2]$, where nitrogen dioxide $[NO_2]$ and nitric oxide [NO] concentrations are in parts per million (ppm), oxygen concentration $[O_2]$ is expressed as a percentage and contact time (t) is in seconds. The rate constants are $k_A = 5.12 \times 10^{-3}$, $k_B = 1.41 \times 10^{-6}$ and $k_C = 0.86 \times 10^{-8}$. Calculated nitrogen dioxide values correlated well with measured concentrations. This new finding of an initial build-up of nitrogen dioxide has to be taken into consideration if the conversion of nitric oxide to nitrogen dioxide is to be calculated and in the safety guidelines for the use of nitric oxide. (*Br. J. Anaesth.* 1998; **80**: 213–217)

Keywords: gases non-anaesthetic, nitric oxide; gases non-anaesthetic, nitrogen dioxide; ventilation, mechanical; complications, pulmonary hypertension

Inhaled nitric oxide has emerged as a therapeutic tool in the management of severe respiratory diseases associated with hypoxaemia and pulmonary hypertension.[1] The main problem during inhalation of nitric oxide is its reactivity with oxygen to form the highly toxic nitrogen dioxide.[2] Nitric oxide reacts with water to form nitric and nitrous acids or it may be absorbed by antioxidants in the lungs, producing new free radicals that participate in and delay the occurrence of lung injuries.[3] The oxidation of nitric oxide has been analysed in sealed chambers and has been found to be dependent on nitric oxide and oxygen concentrations, and contact time of nitric oxide with oxygen according to the equation[4 5]:

$$-d[NO]/dt = k \times [NO]^2 \times [O_2] \qquad (1)$$

The rate constant of this equation has been determined for different humidities and temperatures.[6] The equation is used to state safety guidelines for the use of nitric oxide inhalation[7 8] and it has also been claimed that the equation can be used for calculation of nitrogen dioxide concentration in mechanical ventilation systems.[9]

The aim of this study was to analyse the formation of nitrogen dioxide in a delivery system for inhaled nitric oxide and to formulate a mathematical description of nitrogen dioxide production in such a system.

Materials and methods

A Servo Ventilator 300 (Siemens-Elema AB, Solna, Sweden) which delivers oxygen and air via two gas modules with rapid Servo-controlled valves was used. A third similar gas module delivering nitric oxide to the proximal part of the inspiratory limb was attached to the ventilator (fig. 1). Flow in the three gas modules of the ventilator (air, oxygen and nitric oxide) is synchronized to permit constant concentrations of nitric oxide, independent of oxygen concentration, tidal volume and airway pressure.[10]

The gas source was a high-pressure gas cylinder (160 bar) of nitric oxide (999 ± 20 ppm) mixed in nitrogen (AGA AB, Lidingö, Sweden). Contamination of nitrogen dioxide in the cylinder was guaranteed to be less than 20 ppm.

As accurate measurement was of the utmost importance and we wanted to rule out bias from a single technique of measuring nitric oxide and nitrogen dioxide, we chose to analyse these gases both side-stream and main-stream at a fixed distance from the mixing point. Nitric oxide and nitrogen dioxide were analysed side-stream with a chemiluminescence analyser (ML 9841A Monitor Laboratories, LS Lear Siegler; Measurement Controls Corporation, Englewood, CO, USA) and main-stream with electrochemical fuel cells (CiTicels, City Technology Ltd, City Technology Centre, Portsmouth, UK). Calibration of the chemiluminescence analyser and the electrochemical fuel cells was performed with dry calibration gases containing nitric oxide (82.2 ppm ± 2%) and nitrogen dioxide (6.7 ppm ± 2%) in nitrogen (AGA AB, Lidingö, Sweden). The chemiluminescence analyser is zeroed automatically. The electrochemical fuel cells were zeroed to dry air hourly. The system was flushed with fresh nitric oxide–nitrogen four times before the measurements started to eliminate interference from formed and trapped nitrogen dioxide in the high-pressure tubing.

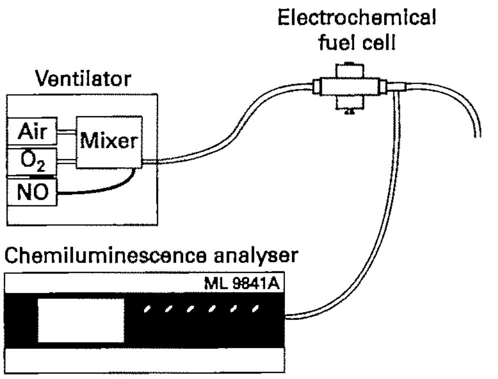

Figure 1 Schematic diagram of the ventilator with paediatric silicon tubes inserted for administering and measuring concentrations of nitric oxide and nitrogen dioxide.

Chemiluminescence analysers use a technique in which nitric oxide reacts with ozone to form excited nitrogen dioxide, which produces a luminescence that is measured spectroscopically. Nitric oxide is measured directly and nitrogen oxides (NO_x) are measured indirectly after passage through a conversion chamber where nitrogen oxides are converted to nitric oxide before measurement. The concentration of nitric oxide produced after the gas has passed this conversion chamber minus the nitric oxide concentration that was directly measured yields the nitrogen dioxide concentration in the sampled gas. Oxygen, carbon dioxide and water vapour can absorb the luminescence, limit the luminescent energy produced and thereby cause underestimation of the actual concentration of nitric oxide and nitrogen dioxide. This process has been referred to as "quenching" and may be more obvious in the measurement of nitrogen dioxide than of nitric oxide.[11] The chemiluminescence analyser was calibrated with nitric oxide–nitrogen dioxide in nitrogen. Measurements were made in gas mixtures of oxygen which introduces quenching and small errors in the measured concentrations of nitric oxide and nitrogen oxides. In order to equate the two measuring techniques, nitric oxide and nitrogen dioxide were measured with the chemiluminescence analyser and electrochemical fuel cells at a standardized point and the measured concentrations were plotted against each other. A linear compensation was made for the difference between the measured concentrations.

Paediatric silicon tubes (diameter 0.009 m) of length 0.9 or 1.47 m were connected to the ventilator. Minute volume ventilation was set at 1, 4, and 7 litre min^{-1} and nitric oxide concentration to 10, 20, 40, 60, 80 and 100 ppm at four different FI_{O_2} values (0.21, 0.4, 0.7 and 0.9). To avoid contamination with room air, we added a 0.6-m tube after the monitors, and the system was open to atmospheric air to avoid pressure dependency (fig. 1).

Contact time of nitric oxide with oxygen was calculated by dividing the volume of the tube system with mean gas flow. Nitrogen dioxide concentrations were plotted against contact time of nitric oxide and oxygen in the inspiratory tube at nitric oxide 10, 50, and 100 ppm and an FI_{O_2} of 0.9.

The oxidation of nitric oxide to nitrogen dioxide and the ultimate nitrogen dioxide concentration in the delivery system was analysed and described by the following formula:

$$[NO_2] = k_A \times [NO] + k_B \times [NO]^2 \times [O_2] + k_C \times t \times [NO]^2 \times [O_2] \qquad (2)$$

where nitrogen dioxide $[NO_2]$ and nitric oxide [NO] concentrations are in parts per million (ppm), oxygen concentration $[O_2]$ is expressed as a percentages and contact time (t) is in seconds. k_A, k_B and k_C are rate constants. The rate constants were determined from 210 different combinations of nitric oxide and oxygen concentrations and contact times by curve fitting analysis. A linear regression analysis was performed between calculated concentrations of nitrogen dioxide and measured values.

The rate constant in equation (1) was also determined from nitric oxide and oxygen concentrations and contact times by curve fitting analysis. A linear regression analysis was performed between calculated and measured concentrations of nitrogen dioxide. The concentration of oxygen was converted to ppm and time to minutes to agree with previously published rate constants.[9]

STATISTICAL ANALYSIS

Curve fitting analysis and linear regression were performed in Statistica 5.0 for Windows (StatSoft, Inc. Tulsa, OK, USA). Difference between methods was assessed by calculating bias (mean difference between two values) and precision (SD of the mean differences) based on the method proposed by Bland and Altman.[12]

Results

The concentration of nitric oxide measured by the chemiluminescence analyser was underestimated by 3.5% and the concentration of nitrogen oxides (NO_x) by 3.4% compared with the electrochemical fuel cells. The measured concentrations of nitric oxide and nitrogen oxides were linearly corrected to compensate for these underestimations. After this correction for oxygen-dependent quenching in the chemiluminescence analyser, concentrations of nitric oxide and nitrogen dioxide measured by the

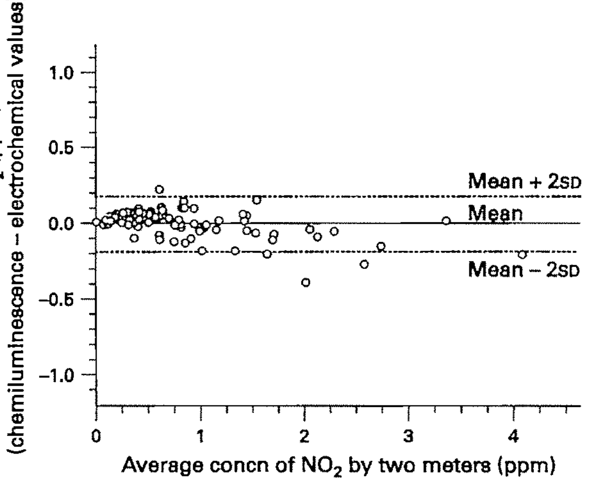

Figure 2 Difference in nitrogen dioxide (NO_2) concentrations measured by the chemiluminescence analyser after correction for quenching and the electrochemical fuel cell, plotted against the mean of the two methods. The limits of agreement (± 0.18 ppm (± 2SD)) are small enough to show that the measurements have good accuracy.

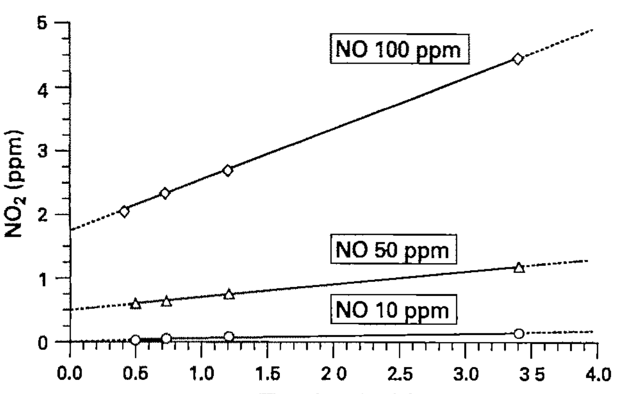

Figure 3 Nitrogen dioxide (NO_2) concentrations measured by the electrochemical fuel cell at different contact times between nitric oxide and oxygen, at nitric oxide concentrations of 10, 50 and 100 ppm and an Fi_{O_2} of 0.9. Note the intercept at time zero.

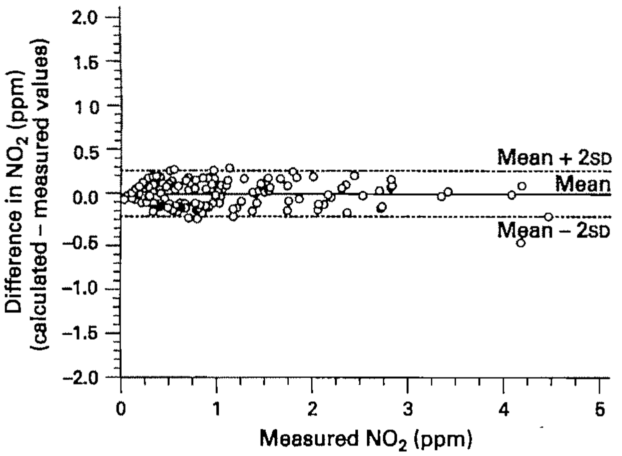

Figure 4 Difference between values of nitrogen dioxide (NO_2) calculated by equation (2) $[NO_2] = k_A \times [NO] + k_B \times [NO]^2 \times [O_2] + k_C \times t \times [NO]^2 \times [O_2]$ and measured, plotted against measured concentrations of NO_2. The limits of agreement (0.29 and −0.22 ppm) are small enough to conclude that the agreement between calculated and measured values is good.

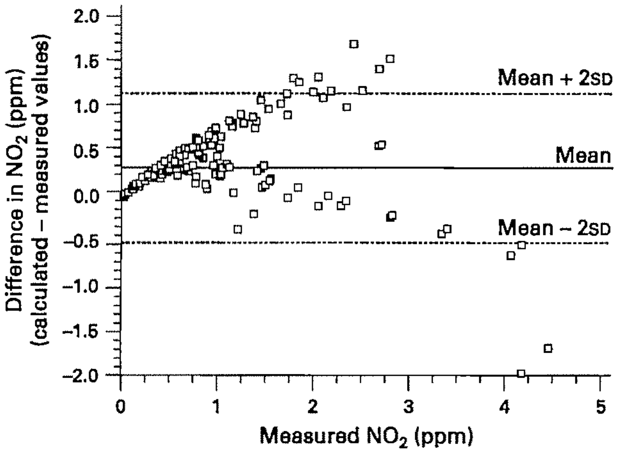

Figure 5 Difference between values of nitrogen dioxide (NO_2) calculated by equation (1) $-d[NO]/dt = k \times [NO]^2 \times [O_2]$ and measured, plotted against measured concentrations of NO_2. The limits of agreement (1.14 and −0.50 ppm) and the plotted values illustrate the lack of agreement between calculated and measured values.

electrochemical fuel cell and the chemiluminescence analyser agreed well. Difference in nitrogen dioxide concentration measured by the chemiluminescence analyser after correction, and the electrochemical fuel cell, was within ± 0.18 ppm (±2 SD) (fig. 2).

The concentration of nitrogen dioxide increased linearly during the contact time of 0.5–3.5 s. At an Fi_{O_2} of 0.9, nitrogen dioxide was produced at an approximate rate of 0.045, 0.21 and 0.8 ppm s^{-1} with nitric oxide 10, 50 and 100 ppm, respectively (fig. 3). Calculated initial concentrations of nitrogen dioxide found by extrapolation of measured concentrations of nitrogen dioxide in figure 3 to contact time zero were 0.031, 0.51 and 1.75 ppm with nitric oxide 10, 50 and 100 ppm, respectively.

The rate constants in equation (2) at 21°C dry gases were: $k_A = 5.12 \times 10^{-3}$, $k_B = 1.41 \times 10^{-6}$ and $k_C = 0.86 \times 10^{-6}$.

Calculated nitrogen dioxide concentrations using equation (2) correlated well with measured nitrogen dioxide concentrations in the system ($r^2 = 0.98$) and showed good agreement when the difference between calculated and measured values was plotted against measured concentration of nitrogen dioxide. The limits of agreement were 0.29 and −0.22 ppm (fig. 4).

The rate constant in equation (1) at 21°C dry gases was 1.89×10^{-6} ppm^{-1} $\%^{-1}$ s^{-1} (11.3×10^{-9} ppm^{-2} min^{-1}). Calculated nitrogen dioxide concentrations using equation (1) correlated less than equation (2) with measured concentrations ($r^2 = 0.82$). A plot of the difference between calculated and measured values against measured concentrations of nitrogen dioxide illustrates the lack of agreement. The limits of agreement were 1.14 and −0.50 ppm (fig. 5).

Nitrogen dioxide concentrations at the Y-piece, with a 0.9-m long paediatric tube and a flow of 2 litre min^{-1} at different mixtures of nitric oxide and oxygen, were calculated according to equation (2) describing nitrogen dioxide production in the delivery system (table 1). Nitrogen dioxide concentrations of 1 and 2 ppm are indicated in order to highlight the concentrations of nitric oxide and oxygen at which these levels were reached.

Discussion

We have found that the previously published equation (1)[5] describing the oxidation of nitric oxide in a closed system with constant concentrations of nitric oxide and oxygen is unsuitable for describing the conversion of nitric oxide to nitrogen dioxide in our delivery system for inhalation of nitric oxide. Our measurements indicate that the oxidation of nitric oxide takes place in two steps, a rapid build-up reaction followed by a linear, time-dependent reaction. A new equation describing the oxidation of nitric oxide to nitrogen dioxide was formulated as a result of the following.

A small contamination of nitrogen dioxide from the nitric oxide stock gas tank contributed to the nitrogen dioxide concentration. As contamination of nitrogen dioxide is dependent on the stock gas concentration of nitric oxide, it was assumed to be proportional to the stock gas concentration of nitric oxide:

$$k_A \times [NO] \quad (2a)$$

An initial build-up of nitrogen dioxide became apparent when the linear, time-dependent increase in nitrogen dioxide concentration was extrapolated to the Y axis (fig. 3). The influence of nitric oxide and oxygen concentrations on this initial build-up of

Table 1 Calculation of nitrogen dioxide concentrations in the delivery system at different nitric oxide and oxygen concentrations, at an inspiratory flow of 2 litre min^{-1} (neonatal) and with a paediatric tube (diameter 0.009 m) with a length of 0.9 m. Nitrogen dioxide concentrations of 1 and 2 ppm are indicated in bold type and bold and underlined type, respectively

nitrogen dioxide, which appears at a contact time of 0–0.5 s, was analysed. Different exponential coefficients for the concentrations of nitric oxide and oxygen were tested in a non-linear multiple regression analysis. The build-up of nitrogen dioxide was found to be directly proportional to the concentration of oxygen and to the square of the nitric oxide concentration, and under this condition was independent of time:

$$k_B \times [NO]^2 \times [O_2] \tag{2b}$$

The linear and time-dependent increase in the concentration of nitrogen dioxide is in agreement with the previously published equation describing the oxidation of nitric oxide with oxygen:

$$k_C \times t \times [NO]^2 \times [O_2] \tag{2c}$$

Theoretically the equation is:

$$k_C \times (1-e^{-t/\tau}) \times [NO]^2 \times [O_2] \tag{2d}$$

where τ = time constant and the factor $(1-e^{-t/\tau})$ shows that as time advances, the rate of change decreases towards zero and the final nitrogen dioxide concentration approaches a final limiting value. The graph of equation (2d) is therefore non-linear. In this case the non-linear behaviour corresponds to the consumption and limited amount of nitric oxide in the gas mix. When all nitric oxide is consumed no more nitrogen dioxide can be formed. For short contact times and small values of nitrogen dioxide, such as appear in a delivery system, the graph appears linear.

The initial production of nitrogen dioxide has not been described in earlier kinetic studies on the reaction between nitric oxide and oxygen.[13] However, it has been noticed that there is an almost instantaneous increase in nitrogen dioxide concentration during air pollution with nitric oxide.[14] One possible reason why this early formation of nitrogen dioxide has not been observed is that kinetic analysis has been carried out in a closed system with a constant concentration of nitric oxide and oxygen in order to avoid the instability that appears during the mixing procedure of the gases. Another reason is that very fast nitrogen dioxide analysers are not available. We were able to estimate the immediate build-up phase by extrapolation.

It seems plausible that the initial production of nitrogen dioxide occurs at the mixing point as a result of a high mixing stock gas concentration of nitric oxide in a fairly high and constant concentration of oxygen. However, it has been noticed that nitrogen dioxide immediately re-forms after a soda lime absorber[15] and that some surfaces have catalytic activity and can increase the rate of nitric oxide oxidation.[14] We used silicon tubes that are claimed not to affect nitric oxide or nitrogen dioxide concentrations.[15] This implies that the mixing concentrations of nitric oxide and oxygen may affect nitrogen dioxide production, but that a rapidly achieved equilibrium in the reaction between nitric oxide and oxygen may explain the initial increase in concentration of nitrogen dioxide.

The agreement between measured and calculated concentrations of nitrogen dioxide also indicates the accuracy of equation (2) and our findings. Equation (2) makes it possible to calculate accurately the concentration of nitrogen dioxide at different set concentrations of nitric oxide and oxygen at different contact times. Documentation of the expected concentration of nitrogen dioxide is of value when set nitric oxide and oxygen concentrations are decided. In table 1 we have calculated nitrogen dioxide concentrations at different set concentrations of nitric oxide and oxygen with settings appropriate to paediatric ventilation, where a high concentration of nitrogen dioxide can be expected. The delivered nitrogen dioxide concentration in the system was always less than 1 ppm if nitric oxide was less than 50 ppm, independent of oxygen concentration, but additional formation takes place in the airway of the patient also, and therefore the alveolar concentration must be expected to be higher.

Equation (1) has been used to calculate and recommend safety guidelines for the use of nitric oxide inhalation. We determined the rate constant of equation (1) and found expectedly that the equation did not accurately describe the concentration of nitrogen dioxide in the delivery system. The rate constant in equation (1) in the current study is higher than has been published previously,[5-8] but similar to the rate constant which Nishimura and co-workers found when nitric oxide was blended with air before introduction into a ventilator.[9] The differences between the rate constants could be because we used a dynamic system where the final concentration of nitrogen dioxide was used for calculation.

Because of the unexpected and previously undescribed finding of a very early high concentration of nitrogen dioxide it was important that accurate measurements were performed. In order to rule out bias from one single technique of measurement we chose to use a chemiluminescence analyser and electrochemical fuel cells. However, both techniques have problems and to equate them we had to compare and analyse measured concentrations.

Electrochemical fuel cells and chemiluminescence analysers are at present the methods of choice to measure nitric oxide and nitrogen dioxide. The chemiluminescence analyser is usually preferred as it offers a more accurate reading of nitric oxide, especially during prolonged measurements. The chemiluminescence technique was designed for environmental monitoring and was not intended to be used in high oxygen environments, but it is also used by gas manufacturers to measure nitric oxide concentration. The effect of quenching was the main reason for the underestimation of measured concentrations of nitric oxide and nitrogen dioxide by the chemiluminescence analyser, but after correction there was good agreement between the chemiluminescence analyser and the electrochemical fuel cells.

Safety guidelines for the use of nitric oxide have referred to kinetic gas reaction analysis in closed systems of constant concentrations of nitric oxide and oxygen, and have therefore exclusively noted the time-dependent oxidation of nitric oxide. An initial build-up of nitrogen dioxide, which seems to appear immediately after mixing of nitric oxide and oxygen, has to be taken into consideration and will result in higher concentrations of nitrogen dioxide than have been assumed previously.

Lidocaine increases the ventricular fibrillation threshold during bupivacaine-induced cardiotoxicity in pigs

Y. Fujita, S. Endoh, T. Yasukawa and A. Sari

Summary

Ventricular fibrillation (VF) is a cause of death in bupivacaine-induced cardiovascular toxicity. We have examined the therapeutic effects of lidocaine on the threshold for bupivacaine-induced VF in *in situ* beating swine hearts. Twenty-four animals were allocated to one of three groups: 0.25% bupivacaine, 1% lidocaine or 0.25% bupivacaine with 1% lidocaine were infused into the left anterior descending coronary artery in increasing doses of 0, 1, 2, 4, 8 and 16 ml h^{-1} for 15 min, respectively. ECG and haemodynamic variables were monitored continuously during infusion. Regional myocardial function in the area supplied by the left anterior descending coronary artery was assessed using the sonomicrometry technique. VF did not occur in the lidocaine group. VF developed at higher infusion rates in animals given bupivacaine with lidocaine (in one animal at an infusion rate of 8 ml h^{-1} and in seven at 16 ml h^{-1}) compared with animals given bupivacaine alone (in one at an infusion rate of 4 and in seven at 8 ml h^{-1}). Although regional myocardial function decreased with increases in the infusion rate in each group, the depressant effects of the bupivacaine solution (medial inhibitory infusion rate of systolic shortening: IR_{50} = 2.43 (0.43) ml h^{-1}) were significantly greater than those of the lidocaine solution (IR_{50} = 5.83 (0.87) ml h^{-1}), but did not differ from those of the bupivacaine with lidocaine solution (IR_{50} = 3.54 (0.56) ml h^{-1}). This study indicates that a combination of lidocaine and bupivacaine increased the threshold for bupivacaine-induced VF without further depressing myocardial contractility. (*Br. J. Anaesth.* 1998; **80**: 218–222)

Keywords: anaesthetics local, bupivacaine; anaesthetics local, lidocaine; heart, arrhythmia, fibrillation; complications, arrhythmia

Bupivacaine-induced cardiotoxicity is characterized by depression of myocardial conductance and contraction. While recent reports,[1-3] including one from our laboratory, have demonstrated that amrinone reverses depressed myocardial contractility, there is no accepted therapy to correct conduction abnormality. Correction or avoidance of conduction abnormality is important because tachyarrhythmias and ventricular fibrillation (VF) caused by bupivacaine-induced cardiotoxicity may be fatal.[4] The mechanism of myocardial conduction abnormality has been explained by the receptor modulated theory.[5] Bupivacaine leads to enhanced myocardial sodium channel block during a cardiac cycle because it dissociates slowly during diastole (fast in, slow out), unlike lidocaine which dissociates from the myocardial sodium channels swiftly during diastole (fast in, fast out). The modulated receptor hypothesis has been extended for a mixture of local anaesthetics which compete for the same binding site of the sodium channel.[6] In an *in vitro* study using guinea pig ventricular myocardium, it has been shown that a drug with rapid binding and unbinding kinetics, such as lidocaine, displaces a drug with slower binding kinetics, such as bupivacaine, resulting in less sodium channel block with the combination of the two drugs than that produced by bupivacaine alone. However, the beneficial effects of lidocaine on bupivacaine-induced cardiotoxicity have not been demonstrated *in vivo*.

We hypothesized that, if the theory is true, *in vivo* the combination of lidocaine and bupivacaine should result in a higher VF threshold than that with bupivacaine alone. As there is a possibility that myocardial contractility might be depressed further by such a combination than by bupivacaine alone,[7] this combination should be examined before clinical use of lidocaine in bupivacaine-induced cardiotoxicity. Therefore, we examined the hypothesis and the effects on myocardial contractility *in vivo* using an animal model similar to that used in our laboratory.[3 8]

Materials and methods

The study was approved by the Animal Research Committee of Kawasaki Medical School (No. 95–048). Twenty-four pigs, weighing 25–43 kg, were anaesthetized with pentobarbital 600 mg i.v. after administration of ketamine 500 mg i.m. The trachea was intubated and the lungs ventilated with a tidal volume adjusted to maintain normocapnia (4.7–5.3 kPa) and a ventilatory frequency of 15 bpm. Anaesthesia was maintained with 50% nitrous oxide and 2–3% sevoflurane during surgical preparation. After instrumentation, sevoflurane was discontinued, and fentanyl was infused at a rate of 0.5 mg h^{-1} to the end of the experiment. Neuromuscular block was maintained with pancuronium 4 mg h^{-1} throughout

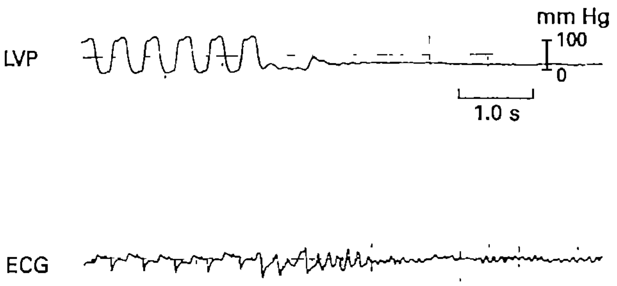

Figure 1 Ventricular fibrillation induced by intracoronary infusion of 0.25% bupivacaine 8 ml h^{-1}. Left ventricular pressure (LVP) and ECG tracing at 25 mm cm^{-1} are shown. Note the widened QRS complex and ST depression R-on-T type PVC preceded ventricular fibrillation.

the study. Rectal temperature was maintained at approximately 37–38 °C by a water blanket.

SURGICAL PREPARATION

The right carotid artery and right external jugular vein were cannulated. Ringer's lactate solution was infused at a rate of 10 ml kg^{-1} h^{-1} during surgical preparation and at a rate of 5 ml kg^{-1} h^{-1} via a venous catheter after surgical preparation. After median sternotomy, a 14-mm ultrasonic transit-time flow probe was placed around the root of the ascending aorta for measurement of cardiac output (CO) via a flowmeter (T208; Transonic Systems Inc., New York, NY, USA). Animals were then turned from the supine to the right lateral position. Left thoracotomy and pericardiotomy were performed through the fifth intercostal space, and the heart was placed in a pericardial cradle. The left anterior descending coronary artery (LAD) was dissected free, proximal to the first diagonal branch, to measure its blood flow (Q_{LAD}) using an ultrasonic flow probe (2 mm in diameter). The value was corrected for myocardial weight. Then a 22-gauge catheter was inserted into the LAD via a puncture and advanced 0.5–1.0 cm in the retrograde direction for infusion of local anaesthetics. Another catheter was placed in the anterior interventricular vein for blood sampling. A pre-calibrated micromanometer catheter (7.5 Fr. Goodtec, Huntington Beach, CA, USA) was inserted into the left ventricle to measure left ventricular pressure through the apex of the heart. Regional myocardial function was evaluated by the sonomicrometry technique, as described previously.[8] A pair of ultrasonic dimension crystals were placed in an equatorial plane into the subendocardium supplied by the LAD for measurement of segmental length. The signals of ventricular pressure and sonomicrometry were digitized at 250 Hz via a computer interface with a 12-bit analogue-to-digital converter and stored for subsequent analysis. The percent systolic segment shortening (SS) was calculated off-line from the following formula: SS = (EDL − ESL) × EDL^{-1} × 100, where EDL= end-diastolic segment length and ESL= end-systolic segment length during a cardiac cycle. SS was normalized to the baseline values of each animal.

STUDY DESIGN

Animals were allocated randomly to one of the following three groups: bupivacaine (Bup: n = 8, mean 27.0 (SEM 0.4) kg), lidocaine (Lid: n = 8, 32.4 (1.4) kg) or bupivacaine with lidocaine (Bup + Lid: n = 8, 33.4 (1.1) kg). One of three saline solutions containing 1% lidocaine, 0.25% bupivacaine or 1% lidocaine with 0.25% bupivacaine, respectively, was infused at increasing rates of 0, 1, 2, 4, 8 and 16 ml h^{-1} for 15 min into the LAD with a syringe pump (STC-521, Terumo, Tokyo, Japan) via the catheter in animals of the corresponding groups. When VF occurred, resuscitation was not attempted and the experiment was terminated. Haemodynamic measurements and blood sampling were carried out after at least 10 min of each infusion rate. Blood samples obtained from the interventricular vein were used for measurement of plasma concentrations of lidocaine and bupivacaine using a fluorescence polarization immunoassay and high-pressure liquid chromatography, respectively.

Table 1 Occurrence of ventricular fibrillation and death during intracoronary infusion of local anaesthetics. There was a significant difference between the bupivacaine (Bup) compared with the bupivacaine and lidocaine (Bup+Lid) group (Mann–Whitney *U* test, $P<0.05$)

DATA ANALYSIS

Data are expressed as mean (SEM). Statistical analysis of data during baseline (0 ml h^{-1} infusion rate) and during infusion of local anaesthetics into the LAD was performed by one-way analysis of variance (ANOVA) followed by Fisher's least significant difference test. Pairwise comparisons on the corresponding steps were performed by Student's *t* test with Bonferroni's correction. The inhibitory infusion rates of local anaesthetics for 50% SS (IR_{50}) were calculated from dose–response curves of normalized SS *vs* infusion rate. The Mann–Whitney *U* test was used to compare the distribution of VF at different infusion rates. $P < 0.05$ was considered statistically significant.

Table 2 Plasma concentrations (mean (SEM)) of local anaesthetics in anterior intraventricular vein blood. Number of samples was 8 except for ^{a}(n=6) and ^{b}(n=2). The reductions in sample numbers were the result of death caused by VF before blood sampling from the anterior intraventricular vein

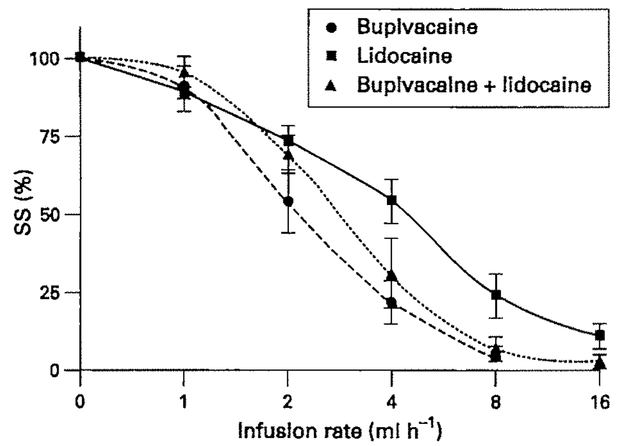

Figure 2 Normalized systolic segment shortening (SS) of the LAD region during intracoronary infusion of local anaesthetics (1% lidocaine, 0.25% bupivacaine or 1% lidocaine with 0.25% bupivacaine). SS decreased in a dose-dependent manner in the three groups. The infusion rate for 50% inhibition of SS (IR$_{50}$) was significantly greater during infusion of lidocaine (5.83 (0.87) ml h^{-1}) than during infusion of bupivacaine or bupivacaine with lidocaine (2.43 (0.43), 3.54 (0.56) ml h^{-1}, respectively).

Results

Mean body weight in group Bup was significantly less than those of the other groups. ECG and LVP tracings made when VF occurred during bupivacaine infusion are shown figure 1. VF was triggered by an R-on-T type ventricular premature beat in all animals without any preceding arrhythmias, except in one animal in group Bup, in which bigeminy developed. No VF occurred in group Lid at any infusion rate (table 1). VF developed in one animal at an infusion rate of 4 ml h^{-1} and in seven at a rate of 8 ml h^{-1} in group Bup, and in one animal at a rate of 8 ml h^{-1} and in seven at a rate of 16 ml h^{-1} in group Bup+Lid. There was a significant difference between groups Bup and Bup+Lid. Table 2 summarizes the mean plasma concentrations in anterior intraventricular vein blood during stepwise increases in intracoronary infusion rates of local anaesthetics. Based on the data in tables 1 and 2, no VF was observed in groups Bup and Bup+Lid at plasma vein concentrations of bupivacaine of less than 2.0 (0.3) and 3.3 (0.3) μg ml^{-1}, respectively. A lidocaine concentration of less than 58.3 (6.7) μg ml^{-1} was not associated with VF.

Substantial ECG changes occurred at higher infusion rates of local anaesthetics (table 3). Widening of the QRS complex with increasing infusion rate was observed at infusion rates of 4 and 8 ml h^{-1} in group Bup, and at 8 and 16 ml h^{-1} in group Bup+Lid, but not in group Lid. PQ and QTc intervals did not change significantly. ST-T wave depression was common with intracoronary infusion of higher doses of local anaesthetics.

Haemodynamic data during intracoronary infusion of local anaesthetics are presented in table 4. There were no significant differences in haemodynamic variables such as HR, MAP, CO and Q_{LAD} between the three groups. Although these variables did not change from baseline during stepwise

increases in lidocaine infusion, significant changes in MAP and CO were observed during higher infusion rates in groups Bup and Bup+Lid. Q_{LAD} began to decrease at an infusion rate of 4 ml h^{-1}.

SS decreased in a dose-dependent manner during intra-coronary infusion of local anaesthetics (fig. 2). The IR_{50} for group Lid (5.83 (0.87) ml h^{-1}) was significantly less than those for groups Bup and Bup+Lid (2.43 (0.43) and 3.54 (0.56) ml h^{-1}, respectively). There was no difference in IR_{50} between groups Bup and Bup+Lid.

Discussion

As the anaesthetic potency of 0.25% bupivacaine is the same as that of 1% lidocaine, a 1% lidocaine with 0.25% bupivacaine solution is twice as potent as a 0.25% bupivacaine solution. Nevertheless, higher infusion rates of the bupivacaine with lidocaine solution were needed for induction of VF compared with those of the bupivacaine solution. Furthermore, the QRS interval in group Bup was widened at an infusion rate of 4 ml h^{-1} compared with baseline values, whereas that of group Bup+Lid did not differ between baseline and an infusion rate of 4 ml h^{-1}. These *in vivo* findings indicate that the threshold for bupivacaine-induced VF was increased and conduction abnormality attenuated in the presence of lidocaine. Therefore, we have confirmed the extended modulated receptor hypothesis *in vivo*. It is speculated therefore that in the event of accidental intravascular injection during regional anaesthesia, the use of a mixture of lidocaine and bupivacaine would result in less conduction abnormality and less chance of VF than would occur with a bupivacaine solution.

However, we did not find any direct evidence to support treatment against bupivacaine-induced cardiotoxicity with lidocaine, because a mixture of bupivacaine and lidocaine was used in this study. Interestingly, it has been reported that lidocaine was effective in conduction abnormality induced by propoxyphene, the major metabolite of which has slow unbinding kinetics with myocardial sodium channels.[9] The accompanying experiment using rabbit atrial myocytes demonstrated that the recovery time for sodium channel block was shortened from 14.3 (2.9) s during exposure to propoxyphene alone to 1.6 (0.9) s during exposure to a lidocaine and propoxyphene mixture. de Jong and Davis[10] reported that lidocaine converted refractory arrhythmias after bupivacaine overdose in cats undergoing ventilation. Based on these reports, we believe that sodium channel block is attenuated, even if lidocaine is administered by the same mechanism, during bupivacaine-induced cardiotoxicity. However, it must be noted that administration of lidocaine has a limitation, because VF occurred in group Bup+Lid at higher infusion rates. Therefore, further studies are necessary to define the limit of lidocaine treatment against bupivacaine-induced cardiotoxicity.

According to the modulated receptor hypothesis, shortening of action potential duration, decreasing heart rate and induction of diastolic hyperpolarization during diastole are thought to effectively minimize accumulation of sodium channel block with bupivacaine.[5] In fact, potassium channel openers have been shown to attenuate atrioventricular block produced by bupivacaine in isolated guinea pig hearts, presumably by shortening of action potential duration and hyperpolarization.[11] These measures are, however, not feasible during routine clinical practice because of their myocardial depressant effects.

Although many drugs, such as magnesium,[12] clonidine,[13] and hexamethonium,[14] have been reported to have a beneficial effect on bupivacaine-induced arrhythmias in experimental studies, their mechanisms have remained speculative. More importantly, these drugs have not been reported to be clinically effective. Epinephrine is often added to local anaesthetics to prevent rapid vascular absorption and to prolong duration of block. It does not, however, protect against bupivacaine-induced cardiotoxicity[15] or even potentiate toxicity.[16] This is explained in part by its arrhythmogenic property. Kasten and Martin[17] showed that bretylium, which is an antifibrillatory agent, but not lidocaine, effectively corrected bupivacaine-induced cardiotoxicity. The discrepancy between their results and ours may be explained by the difference in the experimental model. They examined the effect on ventricular tachycardia threshold using burst ventricular pacing instead of the occurrence of actual VF. Moreover, as bretylium prolongs ventricular action potential duration and increases heart rate because of release of catecholamines, it may enhance bupivacaine-induced sodium channel block and therefore worsen cardiotoxicity.

Even at the highest infusion rate, lidocaine did not cause QRS widening. Moreover, no animal in group Lid died of VF despite a high mean venous plasma concentration of 58.3 (6.7) μg ml^{-1}. This may suggest a greater margin of safety against VF during lidocaine-induced cardiotoxicity. This is consistent with previous reports in sheep by Nancarrow and colleagues.[18] They reported that respiratory depression and hypotension were the causes of death in lidocaine-treated sheep, whereas three of four bupivacaine-treated sheep died after sudden onset of VF or ventricular tachycardia.

The dose–response relationship for SS revealed no difference between groups Bup and Bup+Lid, although SS decreased with increase in infusion rate of local anaesthetics in the three groups. This indicates that inclusion of lidocaine at the same potency did not increase bupivacaine-induced depression of myocardial contractility. In support of these findings, de Jong and Davis showed that hypotension was not precipitated by lidocaine in cats after bupivacaine-induced cardiotoxicity.[10] There were also no significant differences in Q_{LAD}, HR, MAP or CO between groups Bup+Lid and Bup. We conclude that the combined use of lidocaine and bupivacaine is not associated with further depression of myocardial contractility.

We used the selective LAD infusion technique in beating hearts in this study. An advantage of our model was that we could evaluate the direct myocardial effects of drugs without interference of other organs. This is important because bupivacaine-induced cardiotoxicity is enhanced by hypoxia and acidosis[19] caused by convulsion or respiratory depression. However, we admit that this model is affected by the re-entry phenomenon in contrast with the clinical situation where the entire heart is exposed to drugs. This may explain why VF occurred without any arrhythmias in this study except for one case of bigeminy, although it is reported that arrhythmias often precede VF during cardiotoxicity induced with i.v. bupivacaine infusion.[20]

It is notable that mean body weight in group Bup was significantly less than those of the other groups. However, we do not believe that this difference affected the results, because plasma concentrations of bupivacaine and lidocaine in the anterior intraventricular vein were similar in groups Bup and Bup+Lid groups and in groups Lid and Bup+Lid at corresponding infusion rates.

In summary, the results of this study demonstrated that lidocaine increased the threshold of bupivacaine-induced VF without enhancing myocardial depression. We therefore recommend that regional anaesthesia with relatively high doses of local anaesthetics be performed with a mixture including lidocaine rather than with bupivacaine alone. Furthermore, the results of this study suggest that lidocaine might be the drug of choice for bupivacaine-induced cardiotoxicity predisposing to VF.

Anaesthesia for telescopic procedures in the thorax

S. PLUMMER, M. HARTLEY AND R. S. VAUGHAN

Over the past decade, there has been an increase in endoscopic procedures within the thorax for diagnostic and therapeutic purposes. Each has its indications, techniques and complications. However, the one common denominator is that there is always the possibility that thoracotomy may be necessary. Occasionally, particularly if considerable haemorrhage occurs, thoracotomy may be required immediately. Consequently, the clinical examination and investigations should be orientated to this possibility. The medical and theatre staff should be prepared for, and trained to deal with, such an eventuality.

GENERAL PREOPERATIVE CONSIDERATIONS

Patients should undergo a complete evaluation for a full posterolateral thoracotomy. The goal is to define all of the problems and to ascertain if the patient is in the best possible condition. Factors known to increase the risk for patients undergoing thoracic surgery include cigarette smoking, advanced age, coronary artery disease, preoperative weight loss, obesity, poor pulmonary function and duration of anaesthesia.[47]

Cardiac risk is determined by the severity of coronary artery disease, presence of cardiac arrhythmias, left ventricular dysfunction, age and associated medical conditions such as hypoxaemia, diabetes and renal insufficiency.[28] An exercise stress test should be performed as patients with ischaemia are at a higher risk of perioperative cardiac complications and death when undergoing major operations such as pneumonectomy.[22] Consideration should be given to cardiac catheterization and, if appropriate, coronary artery bypass grafting before major lung resection. However, it is not known if this is true for patients undergoing thoracoscopic pulmonary resection.

The preoperative evaluation of the respiratory system involves taking a history, physical examination, exercise tolerance, routine laboratory tests, including arterial blood-gas tensions, radiography and pulmonary function tests. Patients who show an increase in peak expiratory flow rate by 15% or more after administration of bronchodilators should receive perioperative bronchodilators. A forced vital capacity (FVC) of at least three times the tidal volume is necessary for an effective cough and a value of less than 50% of predicted is an indicator of increased risk of postoperative ventilator dependency.[31] A maximum voluntary ventilation less than 50% of predicted is another poor prognostic indicator and indicates possible postoperative atelectasis and infection.[12] In patients with marginal pulmonary function who are considered for lung resection, a quantitative ventilation–perfusion scan is indicated. The percent of perfusion delivered to the lung which is to be resected is multiplied by the preoperative FVC or forced vital capacity in 1 s (FEV_1). Patients who have a predicted postoperative FEV_1 of less than 800 ml are generally considered a prohibitive operative risk. At least 2 u. of blood should normally be available. However, grouping and saving of serum should be sufficient cover for bronchoscopy.

Bronchoscopy

Bronchoscopy is the oldest and most frequently performed endoscopic procedure used in the assessment and management of patients with pathology in the thoracic cavity. It may be rigid or flexible. The first rigid bronchoscopy was performed by Gustav Hillian in 1897. The technique was developed by Chevalier Jackson in the USA and by Victor Negus in the UK in the early years of the 20th century. The flexible fibreoptic bronchoscope was introduced into clinical practice by Shigeto Ikeda in 1968.

The roles of rigid and flexible fibreoptic bronchoscopy in current clinical practice have been reviewed.[25] Although rigid bronchoscopy has generally been superseded by flexible fibreoptic bronchoscopy for the initial assessment of airway and thoracic disease, it remains the procedure of choice for surgical assessment before staging procedures such as mediastinoscopy and before thoracotomy. The rigid bronchoscope is also the preferred instrument for use in small children, in adults with massive haemoptysis and for therapeutic procedures such as foreign body removal, stent insertion and endoscopic resection of airway tumours.

PREOPERATIVE ASSESSMENT

A full history and clinical examination are essential. Patients who require bronchoscopy are frequently cigarette smokers with hyper-reactive airway reflexes and are likely to have impaired cardiovascular and

respiratory function. Preoperative assessment should be directed to the identification of such patients and to optimal control of co-existing medical conditions.

Preoperative investigations should include routine haematology and biochemistry, a 12-lead electrocardiograph in adults and a chest radiograph in all patients. More advanced imaging of the chest, such as computerized tomography or magnetic resonance scanning, in addition to pulmonary function tests and arterial blood-gas analysis may also be appropriate. If bronchoscopy is to be performed immediately before thoracotomy, such investigations are mandatory.

The chest radiograph is particularly important as it demonstrates areas of pulmonary collapse and consolidation, and highlights the presence of an air-filled cavity such as a lung bulla or a pneumothorax. In a patient who has inhaled a foreign body, chest radiographs performed at the end of inspiration and expiration may reveal an emphysematous area distal to the site of the foreign body. This indicates that the foreign body is acting as a "ball valve" in the lower airway, allowing air entry during inspiration but preventing the exit of the same volume of air during expiration. This radiographic finding contraindicates the use of nitrous oxide and positive pressure ventilation during general anaesthesia as a consequence of their potential to increase the size of an air-filled cavity, which may result in both respiratory and cardiovascular embarrassment. This is particularly important in children

PREMEDICATION

Premedication should include the patient's regular cardiovascular and respiratory medications. Diabetic patients should omit their usual oral antidiabetic medication. Those who are insulin-dependent should be managed using an i.v. glucose–insulin regimen. Particular attention should be paid to the preoperative control of bronchospasm as perioperative morbidity and mortality are particularly high in such patients.[51]

A short-acting benzodiazepine may be administered to relieve preoperative anxiety without delaying recovery of consciousness at the end of the procedure. Sedative agents should, however, be avoided in the presence of upper airway obstruction. An anticholinergic agent may be administered to counter the muscarinic effects of the anaesthetic drugs to be used and the surgical procedure.

MONITORING

Minimum monitoring is essential for both flexible fibreoptic and rigid bronchoscopy, whether the procedure is to be performed with sedation and local anaesthesia or with general anaesthesia, as cardiovascular and respiratory complications are common.[51] Minimum monitoring should comprise an electrocardiograph, an intermittent non-invasive method to measure arterial pressure and continuous pulse oximetry to measure arterial oxygen saturation. Capnography should also be used during flexible fibreoptic bronchoscopy under general anaesthesia, but is not easily adapted for use with the unsealed airway during rigid bronchoscopy. Monitoring should always be attached before administration of sedative or anaesthetic agents and continued until the patient has recovered fully from the procedure. In future, the use of transcutaneous carbon dioxide monitoring may be an appropriate alternative, particularly in children and during prolonged procedures.

FLEXIBLE FIBREOPTIC BRONCHOSCOPY

The flexible fibreoptic bronchoscope is available in varying sizes for use both in children and adults. Passage of the bronchoscope via the nose or mouth is a relatively atraumatic procedure and can be performed under sedation and topical anaesthesia in the majority of patients. General anaesthesia is reserved for children and those adults who are unable to tolerate the procedure awake.

Sedation is usually provided by a combination of a benzodiazepine and an opioid. Propofol by continuous infusion may also be used safely as a sedative for flexible fibreoptic bronchoscopy.[20] If passage of the bronchoscope via the nose is required, the nasal mucosa can be anaesthetized using either cocaine or one of the newer local anaesthetic agents in combination with a vasoconstrictor. A detailed description of the methods available to produce topical anaesthesia of the lower respiratory tract is beyond the scope of this review. In practice, local anaesthetic agents may be effectively administered by nebulization, cricothyroid puncture or using a "spray as you go" technique.[42] Large doses of local anaesthetic agents are required for effective topical anaesthesia. Systemic absorption resulting in local anaesthetic toxicity is a significant risk.[44]

In the anaesthetized patient, the flexible fibreoptic bronchoscope is usually introduced into the trachea via a self-sealing diaphragm in the angle piece attached to a tracheal tube. Ventilation of the lungs with an anaesthetic gas mixture of known concentration can be continued around the outside of the bronchoscope but within the lumen of the tracheal tube. The presence of the bronchoscope within the tracheal tube reduces the available internal cross-sectional area and increases resistance to the flow of gas via the tracheal tube. Consequently, it is important to use the largest feasible tracheal tube in each individual patient. It is also usual to administer neuromuscular blocking agents and to control ventilation, a technique which has been shown to maintain satisfactory gas exchange.[49]

The laryngeal mask airway (LMA) has also been used as a conduit for the flexible fibreoptic bronchoscope in both awake and anaesthetized patients.[5 13] Although the internal cross-sectional area of the shaft of the laryngeal mask airway is greater than that of a corresponding tracheal tube, consideration should be given to the increase in resistance to gas flow produced by insertion of the bronchoscope and the requirement for controlled ventilation.

An alternative approach involves the passage of the flexible bronchoscope into the upper airway of a spontaneously breathing patient via either the diaphragm of an angle piece attached to an anaesthetic face mask,[46] or via a second aperture on a modified face mask, such as the Patil Syracuse mask.[63] This technique avoids the problem of a reduced space for ventilation between the internal

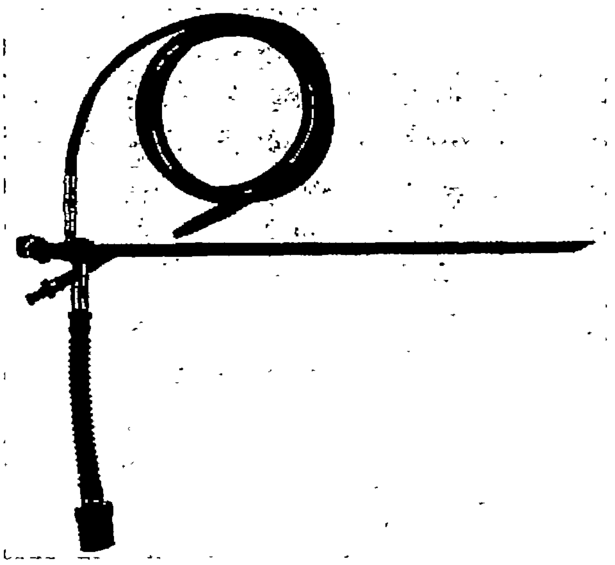

Figure 1 The Storz bronchoscope with a standard breathing system.

wall of the tracheal tube or laryngeal mask airway and the fibreoptic bronchoscope.

RIGID BRONCHOSCOPE

The original rigid bronchoscopes were open-ended, tapered metallic tubes, available in a variety of sizes. Side-holes down the body of the bronchoscope were incorporated later to allow bilateral lung ventilation when the tip of the bronchoscope was in one of the major bronchi. Further modifications to this basic design led to the development of the rigid ventilating bronchoscopes used in current practice which can use a breathing system or a Venturi system to achieve ventilation.

The rigid ventilating bronchoscope incorporates a sidearm adapter which can be attached to an anaesthetic breathing system (fig. 1). Occlusion of the proximal end of the bronchoscope by an eyepiece allows spontaneous or controlled ventilation to occur through the lumen of the bronchoscope. There is a variable gas leak around the bronchoscope.

The rigid bronchoscope which uses the Venturi principle incorporates a needle within its lumen and runs parallel to its long axis (fig. 2). Release of gas from a high pressure source via the needle entrains environmental gas through the proximal open end of the bronchoscope and allows controlled ventilation to occur through the lumen of the bronchoscope.

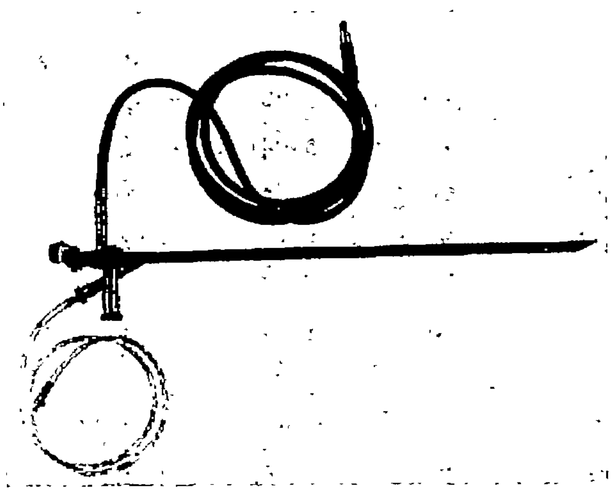

Figure 2 The Storz bronchoscope with the Sanders injector.

In contrast with flexible fibreoptic bronchoscopy, rigid bronchoscopy produces a considerable amount of mucosal stimulation, pressure on soft tissues and requires significant extension of the cervical spine. Consequently, this procedure is almost always performed under general anaesthesia. In children, it is advisable that a laryngoscope is used to expose the vocal cords which may also be sprayed with local anaesthetic solution. Such exposure also allows the endoscopist to introduce the correct size bronchoscope with minimum delay and reduces the chances of trauma to the cords.

Patients are able to breathe or their lungs can be ventilated around the flexible fibreoptic bronchoscope. In contrast, the rigid bronchoscope is hollow and patients must either breathe or undergo ventilation through it. The performance of rigid bronchoscopy under general anaesthesia therefore requires that the responsibility for the management of the airway be shared between the anaesthetist and the endoscopist. The anaesthetist must maintain adequate oxygenation and carbon dioxide elimination during a procedure that inevitably interferes with airway and respiratory function.

ANAESTHETIC TECHNIQUES

Rigid bronchoscopy can be performed in the spontaneously breathing patient under a deep plane of anaesthesia using an inhalation anaesthetic agent. This remains a popular technique in some centres for children and for adults with upper airway obstruction. Meretoja and colleagues have recently compared sevoflurane in oxygen and nitrous oxide with halothane in oxygen and nitrous oxide for induction and maintenance of anaesthesia in infants and children undergoing rigid bronchoscopy or gastroscopy.[56] In the sevoflurane group, induction and recovery times were shorter and there were significantly fewer complications, particularly arrhythmias and laryngeal spasm.

Complications of performing rigid bronchoscopy in spontaneously breathing patients range from laryngeal spasm and bronchospasm caused by inadequate anaesthesia, to hypoventilation as a result of excessive anaesthesia. As a consequence, it is common practice to administer an i.v. anaesthetic agent, a neuromuscular blocking agent and to use intermittent positive pressure ventilation. Anaesthesia is maintained by administration of either an inhalation agent, increasingly sevoflurane or an i.v. anaesthetic agent, increasingly propofol. As the inspired oxygen and inhalation anaesthetic agent concentrations are known with a ventilating bronchoscope but not known using the Venturi system bronchoscope, rigid ventilating bronchoscopy can be performed with either inhalation or i.v. anaesthesia. However, rigid bronchoscopy using the Venturi system is best performed under total i.v. anaesthesia using an $F\text{I}_{O_2}$ of 1.0. Intermittent bolus doses of methohexital, etomidate, thiopental and propofol have been used for this purpose.[38 53 82] The problems of using these i.v. techniques include awareness caused by administration of inadequate increments of anaesthetic agent and delayed recovery as a result of administration of excessive anaesthetic agent.[3,21] It is preferable, therefore, for all but the shortest procedures, to administer the i.v. anaesthetic agent by continuous infusion. Alfentanil followed by infusion of propofol has been shown to provide satisfactory anaesthesia for bronchoscopy without awareness during the procedure, with a rapid postoperative recovery.[45]

The haemodynamic responses to rigid bronchoscopy have been the subject of several studies. These responses are qualitatively similar to the responses caused by direct laryngoscopy and tracheal intubation, but may be of greater magnitude and longer duration.[82] Significant increases in heart rate, systolic and diastolic arterial pressures follow rigid bronchoscopy after thiopental but not propofol anaesthesia.[58] Myocardial ischaemia may occur during general anaesthesia for rigid bronchoscopy with or without the development of significant haemodynamic abnormalities.[58,82] The addition of a small dose of an i.v. opioid partially controls the haemodynamic responses caused by rigid bronchoscopy after thiopental but is superfluous after propofol.[3,58] Others use the ultra-short-acting β blocker esmolol to attenuate the responses to both bronchoscopy and endobronchial intubation.[74,80] There is no evidence that the use of anticholinergic agents to control airway secretions aggravates the haemodynamic response to rigid bronchoscopy.[33,52]

Neuromuscular block for rigid bronchoscopy may be produced by a variety of agents. The choice is determined by the anticipated duration of the procedure. The depolarizing agent succinylcholine remains popular for short procedures, although the short-acting non-depolarizing agent mivacurium is a suitable alternative. If bronchoscopy is expected to be prolonged or is to be followed by a surgical procedure, a longer acting non-depolarizing neuromuscular blocking agent may be used.

Administration of a local anaesthetic agent to the vocal cords and trachea before rigid bronchoscopy under general anaesthesia has been recommended to prevent laryngeal spasm after the bronchoscope is removed.[19] However, the only study of this practice did not demonstrate any advantage when 4% lignocaine 4 ml was sprayed onto the larynx before bronchoscopy.[1] Furthermore, the associated depression of the cough reflex is undesirable, particularly when excessive secretions or haemorrhage develop after bronchoscopy.

Gas exchange in the anaesthetized and paralysed patient may be produced using a variety of methods: (1) apnoeic oxygenation; (2) rigid ventilating bronchoscopy; (3) rigid bronchoscopy with Venturi attachment; (4) high frequency jet ventilation; and (5) use of the Hayek oscillator

(1) Apnoeic oxygenation

Insufflation of oxygen via a catheter placed into the lower trachea is a satisfactory method of maintaining oxygenation in a patient who has been preoxygenated, anaesthetized and paralysed for rigid bronchoscopy.[17,29] The technique is limited by the development of progressive hypercapnia and respiratory acidosis, Pa_{CO_2} increasing at a rate of 0.5 kPa (3–5 mm Hg) per minute.[23,29,84]

(2) Rigid ventilating bronchoscope

The rigid ventilating bronchoscope was developed to provide conditions similar to tracheal intubation.[57,69] It incorporates at its proximal end a side port which can be attached to an anaesthetic breathing system, allowing continuous flow of anaesthetic gases and vapours. Occlusion of the proximal end of the bronchoscope by a sliding eyepiece allows spontaneous or controlled ventilation to occur via the lumen of the bronchoscope. There is a variable flow of gas around the distal end of the bronchoscope, compensated for by providing a high fresh gas flow or by packing the laryngopharynx.

The major disadvantage of the rigid ventilating bronchoscope is that the sliding eyepiece must be removed during surgical manoeuvres such as suctioning or obtaining biopsy specimens. These interruptions to ventilation inevitably result in progressive hypercapnia and respiratory acidosis when the rigid ventilating bronchoscope is used in the anaesthetized, paralysed patient.[32,58] Pollution is also a problem as scavenging is almost impossible with this system.

(3) Rigid bronchoscope using the Venturi principle

The first rigid bronchoscope using the Venturi principle was described by Sanders in 1967.[70] He developed an attachment applied to the proximal end of an open bronchoscope which used the energy of compressed oxygen exerted through an injection needle placed inside and running parallel to the long axis of the bronchoscope. Environmental air was entrained by the Venturi effect and generated a pressure within the bronchoscope sufficient to inflate the lungs with a variable oxygen–air mixture. A pressure regulator was required to maintain a constant pressure and the flow was controlled by a manually operated on–off valve placed in the line connecting the pressure regulator to the attachment. Uninterrupted controlled ventilation could be achieved without occlusion of the open end of the bronchoscope and without interference with vision or instrumentation through the bronchoscope. Sanders stated that the use of this device maintained oxygenation without producing hypercapnia and respiratory acidosis. This was subsequently confirmed by several detailed studies.[32,64,71]

Spoerel and Grant established that the pressure produced at the distal end of the bronchoscope by the Sanders device varied with the volume of oxygen flow into the bronchoscope. This is determined by the driving pressure from the reducing valve, the size of the injector needle, and the diameter, length and type of bronchoscope.[73] The tidal volumes generated in an individual are thus dependent on the pressure produced at the distal end of the bronchoscope, the size of the leak around the bronchoscope and compliance of the lungs.

To avoid lung barotrauma, it is important to match the volume of oxygen flow into the bronchoscope to the diameter, length and type of bronchoscope in use. This may be achieved by altering either the driving pressure or the size of the injector needle. In practice, it is usual to maintain a constant driving pressure and adjust the size of the injector needle.

Bethune and colleagues determined the maximum pressures generated in the Negus range of bronchoscopes with varying sizes of injector needle and a driving pressure equal to the standard oxygen pipeline pressure of 410 kPa. A 16-SWG needle is suitable for adults, a 18-SWG needle for adolescents and a 19-SWG needle for children, infants and neonates.[10] A 14-SWG needle may be required in adults with poor compliance in order to achieve the high inflation pressures necessary to produce adequate tidal ventilation.[9]

Carden, Trapp and Oulton described a modification of the original device in which oxygen was injected through the sidearm of the bronchoscope with little or no air entrainment.[16] Subsequent comparison of this system with the Sanders device has confirmed that the sidearm system delivers much higher oxygen concentrations and therefore, results in high Pa_{O_2} concentrations without producing hypercapnia and respiratory acidosis.[14] This system may also be used to deliver a premixed nitrous oxide–oxygen gas mixture.[15]

It is essential when using any bronchoscope with a Venturi system that the proximal end of the bronchoscope remains open to allow entrainment of air during inspiration and escape of gas during expiration. Otherwise, lung barotrauma may result.

(4) High frequency jet ventilation

The use of high frequency ventilators to produce high frequency–low volume ventilation via the sidearm of the rigid bronchoscope has been shown to achieve suitable operating conditions and adequate gas exchange at rates up to 300 bpm.[79] The technique is popular in some countries, but is not widely used in the UK.

(5) The Hayek oscillator

Rigid bronchoscopy has been performed under general anaesthesia with muscle paralysis and external negative pressure ventilation produced by the Hayek oscillator.[60] There would appear to be no detriment to gas exchange in the lungs. In addition, the endoscopist had total freedom for the investigation as there are no attachments to the bronchoscope whatsoever. This arrangement would also be of benefit during laser therapy to the respiratory tract.

POSTOPERATIVE CARE

At the end of the procedure, administration of anaesthetic agents should be discontinued, 100% oxygen given and the residual effects of non-depolarizing neuromuscular blocking agents antagonized with an anticholinesterase. If a general anaesthetic has been administered, it is advisable to perform direct laryngoscopy and, if necessary, use a suction catheter to clear secretions, blood or other debris from the upper airway. The bronchoscope is removed from the airway before re-establishing control of the upper airway with either a face mask and oropharyngeal airway, a laryngeal mask airway or insertion of a tracheal tube. In the presence of infection or haemorrhage after a biopsy, the patient should be placed *with the bad lung* down to protect the good lung until the cough reflex returns. The patient should be allowed to recover by breathing a humidified oxygen-enriched air mixture before transfer to a fully monitored recovery area.

COMPLICATIONS

Complications of flexible fibreoptic and rigid bronchoscopy can be classified conveniently into three groups.

Anatomical

Damage to teeth or dental work is not an uncommon occurrence during bronchoscopy. Direct trauma to other structures in the upper and lower airways may result in haemorrhage, oedema or tumour fragmentation which may compromise the airway. Mucosal perforation may lead to subcutaneous emphysema, mediastinal emphysema or tension pneumothoraces.[30] Such complications are particularly likely during bronchoscopic biopsy. An emergency thoracotomy may be required to repair the damage.

Mucosal disruption leading to subcutaneous emphysema, mediastinal emphysema and tension pneumothoracies may also develop as a consequence of barotrauma.[62] Lung barotrauma is particularly likely to occur if a bronchoscope using a Venturi attachment is used carelessly, especially in children, where the escape of gas around the bronchoscope is limited because of a tight fit of the bronchoscope in the glottis.

Physiological

Arrhythmias are frequent during bronchoscopy.[51] Bradycardia occurs as a vagally mediated response to insertion of the bronchoscope and may necessitate i.v. administration of an anticholinergic agent. Other arrhythmias are the result of catecholamines produced in response to the surgical stimulus. Hypoxia and hypercapnia may contribute to these arrhythmias and should be corrected before specific antiarrhythmics are administered.

After extubation

The development of upper airway obstruction may complicate the recovery period. The commonest causes are laryngeal spasm, masseter spasm or laryngeal oedema . Management of these complications has been reviewed recently,[34] and algorithms have been proposed for their treatment.[34 76]

Mediastinoscopy

Mediastinoscopy, originally described by Carlens in 1959,[11] is performed for two major reasons: first, to obtain tissue for histological diagnosis, and second, to stage lung malignancy. A histological diagnosis is very important as a lymphoma is treated with radiation while a thymoma, for example, requires resection. A diagnosis of tuberculosis or sarcoidosis will also lead to correct treatment.

The majority of mediastinoscopies are performed via the neck, entering the mediastinum behind the manubrium—the so-called cervical mediastinoscopy. The second, and less common approach, is through the second left interspace (the anterior approach) to inspect the lower left mediastinum.[40] The former approach is more difficult and has a greater complication rate for several reasons.

- Compression of the trachea and major blood vessels by the mediastinoscope, particularly on the right side. This may lead to a decrease in both venous return and flow to the right carotid and subclavian arteries.
- Torrential haemorrhage from biopsy sites which can lead to acute exsanguination requiring emergency thoracotomy.[77] The main reason for such an event is that as the mediastinal glands enlarge, blood vessels become stretched over them and can appear as an integral part of the mass. Biopsy can cause blood vessels to divide, the cut ends part and bleed profusely into the mediastinum. Furthermore, it may prove difficult to replace blood loss from cannulation sites in the arms and upper body as any fluids used during resuscitation pour into the mediastinum. Hence, it is mandatory to have: two large venous cannulae, one in the arm and the other in the leg; and at least 2 u. of crossed matched blood in theatre before the operation commences.

Other complications that may arise from either approach have been summarized by Benumof[5] (table 1).

PREOPERATIVE ASSESSMENT

The anaesthetic management of patients presenting for mediastinoscopy depends on the clinical condition and awareness of possible anaesthetic and surgical complications. These patients can present with a variety of symptoms.

- None: a mass had been noticed on routine chest x-ray.
- Dyspnoea: this symptom has increased over the past few months. These patients feel increasingly uncomfortable if they lie flat.
- Superior vena cave obstruction: this can present as dyspnoea, fullness of the face, ankle swelling and as a bluish colour of the upper part of the body. These patients have great difficulty in lying flat.
- Dry cough and possible stridor: these may be indications of tracheal involvement.
- Increasing muscle weakness: this may be associated with a thymoma and possibly a myasthenic syndrome.

The preoperative clinical assessment enables the anaesthetist to obtain these relevant symptoms. Standard haematological and biochemistry investigations in additon to arterial blood-gas tensions and basic lungs function tests should be available. Computed tomographical scans of the neck, thoracic inlet and chest have superseded the older imaging techniques.

Table 1 Major complications of mediastinoscopy (by kind permission of J. L. Benumof)

- Haemorrhage
- Pneumothorax
  - Recurrent laryngeal nerve injury
  - Air embolism
  - Compression of vessels
    - a. Aorta → reflex bradycardia
    - b. Innominate artery
    - Right carotid → hemiparesis
    - Right subclavian → loss of right radial pulse
  - Compression of trachea
  - Infection, tumour spread

PREMEDICATION

A variety of premedications have been used with few adverse effects, although light oral premedication with a benzodiazepine is currently favoured. No premedication is given in the presence of tracheal compression.

ANAESTHETIC TECHNIQUES

Mediastinoscopy can be performed under sedation and local analgesia but this is generally no longer practised.[59]

The ideal general anaesthetic should produce profound depression of laryngeal and tracheal reflexes followed by rapid recovery. Whichever technique is used, it is essential that minimum monitoring is established. The arterial pressure cuff however, is always applied to the right arm. The right radial artery can also be cannulated under local anaesthesia to provide a continuous display of arterial pressure. Thereafter, the techniques depend on the clinical condition.

Mediastinoscopy in a patient with no symptoms or signs

Preoxygenation is followed by i.v. induction using propofol. A short-acting neuromuscular blocking agent such as vecuronium is given. The cords may be sprayed with lidocaine and the anaesthetist intubates the trachea with a reinforced tracheal tube. A short-acting opioid such as alfentanil can be used.

Mediastinoscopy in the presence of venous congestion

A similar technique can be used but the inflation pressures required to ventilate the patient's lungs should be kept to the minimum to prevent further undue decreases in venous return. I.v. opioids are best avoided.

Mediastinoscopy in the presence of respiratory obstruction, myasthenic syndrome, or both

An awake intubation under local anaesthesia is the technique of choice. Alternatively, inhalation induction is used and a reinforced tube introduced into the trachea under deep anaesthesia after the vocal cords have been sprayed with a local anaesthetic agent. An opioid is contraindicated.

MAINTENANCE

The use of non-depolarizing neuromuscular blocking agents is generally considered essential as the preferred maintenance technique involves intermittent positive pressure ventilation using oxygen, nitrous oxide and a volatile agent. Furthermore, non-depolarizing agents such as vecuronium and atracurium have been used in the presence of myasthenia gravis provided the doses are reduced and neuromuscular activity is monitored using the train-of-four sequence.[41] In the future, sevoflurane and remifentanil will possibly be the drugs of choice because of their rapid onset of anaesthesia and rapid recovery. The patient is placed in a slight head-up position to try and reduce congestion in the great veins. Before the start of the surgical procedure, a large venous cannula should be established in the lower limbs.

MONITORING

Minimum monitoring is used but arterial pressure in the right arm must be constantly measured for two reasons: (1) to note any compression of the right common carotid artery; and (2) to note any decline in pressure associated with possible blood loss.

The gauge on the ventilator must also be noted for two reasons: (1) to use the lowest pressures compatible with high saturation and normal end-tidal carbon dioxide; (2) to note any acute increases in pressure which are usually associated with tracheal compression.

If compression of either the trachea or vasculature occurs, the surgeon must be informed immediately and told to either remove or reposition the mediastinoscope.

COMPLICATIONS

The most serious complication is haemorrhage after a perforated vessel. This can be treated by two methods.

(1) The mediastinum can be packed with swabs soaked in a weak epinephrine solution. Vital signs are monitored constantly. If these remain constant, the swabs are removed after 10 min and the mediastinoscope reintroduced to inspect the damage. If the bleeding has stopped, a drain is left in the mediastinum for at least 24 h.
(2) If the bleeding continues, arterial pressure begins to decrease and heart rate increases, then a thoracotomy is required. It is recommended that a posterolateral approach is used. Under such emergency circumstances it may be ill advised to replace the reinforced tube with a double-lumen endobronchial tube as this may cause undue delay. In addition, blood for resuscitation and replacement may be better infused via the large venous cannula in the lower limb. The tear or hole in the blood vessel is repaired as rapidly as possible.

Air embolism is an important consideration but is extremely rare as most patients are ventilated artificially. If it does occur and is clinically significant, the patient should be placed in the left head-down lateral position and treated accordingly.

POSTOPERATIVE MANAGEMENT

Neuromuscular block is antagonized, 100% oxygen is given and the tracheal tube removed when appropriate. Patients are transferred to the recovery room, breathing oxygen-enriched air. They receive routine monitoring and are sat up as soon as is possible. Those patients who have had a thoracotomy are managed along the lines set out at the end of this review.

Oesophagoscopy

This investigation is performed for three main reasons namely[24]: (1) diagnosis, particularly of carcinoma; (2) removal of a foreign body; and (3) therapeutic, for example injection of oesophageal varices or dilatation of a stricture. Very rarely, it is performed to identify the origin of an oesophageal pouch.

The major problems associated with this investigation are: fluids, blood and solids proximal to the lesion; possible regurgitation of stomach contents; and perforation of the oesophagus.

PREOPERATIVE PREPARATION

Many of the patients are elderly, with the additional problems of multiple treatments (e.g. digoxin and diuretics). Furthermore, some of these patients may be dehydrated as a result of dysphagia, and rehydration is required. Recently, however, preoperative chemotherapy has usually enabled many of these patients to be able to swallow and to return to a normal fluid and electrolyte balance.

PREMEDICATION

It is inadvisable to administer oral premedication. The main reasons are that the drugs may stay in the oesophagus proximal to the lesion and cause retching. Premedication is therefore either avoided or given i.m. Because of possible difficulties in swallowing, antacids are rarely used. However, there are reasonable grounds for using i.v. agents which reduce gastric secretions and increase gastric emptying.

INDUCTION

The investigation can be performed under sedation and local analgesia or general anaesthesia.[66] Minimum monitoring is mandatory for each procedure.

Sedation and local analgesia

There are a variety of techniques available. Most use i.v. sedation (e.g. midazolam) and topical analgesia to the upper respiratory and oesophageal tracts. A fibreoptic oesophagoscope is generally used for inspection and therapeutic procedures. The safety of such procedures has been addressed.[66 67] However, the fibrescope cannot be used to remove foreign bodies or in children.

General anaesthesia

Several agents have been used to induce anaesthesia after a suitable period of preoxygenation. A rapid sequence technique is used with succinylcholine and cricothyroid pressure. The trachea is intubated with a reinforced tube which is moved to the left side of the mouth to permit passage of either a rigid or flexible oesophagoscope. The rigid variety can compress a standard tracheal tube. Most anaesthetists do not wait for the action of succinylcholine to "wear off" before giving a short acting non-depolarizing neuromuscular blocking agent. The reason for this approach is that coughing can increase the chances of the major complication of this procedure namely, oesophageal perforation. Inflation pressures are monitored continuously but additional vigilance is required in children during oesophagoscopy as there are no suitably sized reinforced tracheal tubes available. On rare occasions, when an oesophageal pouch is present, a CT scan is mandatory so that the anaesthetist can position the patient appropriately before induction. The patient is placed in either the left or right semi-lateral positions with the pouch of the sac lowermost. Occasionally, a full lateral position is required. The object is to contain any fluid or solids in the sac until intubation has been accomplished. Cricothyroid pressure is not effective in containing the contents in the sac. Indeed, some may argue that the manoeuvre itself may compress the sac and cause the contents to enter the pharynx.[78]

MAINTENANCE

Anaesthesia is usually maintained with oxygen, nitrous oxide and a volatile agent using intermittent position pressure ventilation. Continuous i.v. propofol is also an acceptable technique. The use of i.v. opioids is optional. Two key monitors are: (1) the ECG, which can show the occasional arrhythmia which is generally not significant; and (2) inflation pressures, which must be monitored continuously to detect compression of the tracheal tube.

POSTOPERATIVE MANAGEMENT

Neuromuscular block is antagonized and 100% oxygen is administered until spontaneous ventilation returns. The trachea is normally extubated in the head-down left lateral position. Patients are transferred to the recovery room breathing oxygen-enriched air. A chest x-ray is always obtained to ensure that there has been no oesophageal perforation. Most surgeons do not allow their patients to drink any fluids for 12 h, some even for 24 h, and maintain hydration by the i.v. route.

Thoracoscopy

PRINCIPLES

The first series of thoracoscopy cases were reported in 1921. The Swedish physician, Jacobaeus, used the technique to treat pulmonary tuberculosis and pleural effusions.[43] The development of antibiotics to treat tuberculosis led to virtual cessation of thoracoscopic procedures. Recent advances in endoscopic surgical equipment and refinement of surgical techniques have expanded the role of thoracoscopy to include multiple procedures that previously could only be performed by open thoracotomy.[18 48 57 75 81] The major cause of morbidity after thoracotomy is the incision and associated spreading of the ribs even in limited and muscle-sparing procedures.[36]

Thoracoscopy provides access to the thoracic cavity, is associated with reduced morbidity and does not appear to compromise the procedure.[54] Subsequent studies have confirmed reduced postoperative pain, faster recovery to preoperative functional status and reduced hospital stay after procedures ranging from lung biopsy to lobectomy.[26 50 61 68 83]

Thoracoscopic procedures are currently used to aid the diagnoses of pleural, lung and oesophageal disease, and to assess the extent of lung trauma. Therapeutic uses include lung resection, laser ablation of emphysematous bullae, oesophageal resection, pericardectomy, sympathectomy, removal of mediastinal masses and some spinal surgery. The anaesthetist is therefore faced with establishing one-lung anaesthesia, the associated complications and the potential for a "minimally invasive", but often lengthy, procedure, which may be rapidly converted into an open thoracotomy.

PATIENT CHARACTERISTICS

It is often high-risk patients who are referred for thoracoscopy with the assumption that the procedure produces less physiological trespass. Barker and colleagues[2] anaesthetized 40 such patients for thoracoscopic laser ablation of emphysematous bullae. The patients were elderly smokers with a high incidence of cardiovascular disease who were "respiratory cripples" with little or no exercise tolerance. They tolerated one-lung ventilation better than expected and had stable haemodynamics. However, they did not have prolonged perioperative courses.

PREOPERATIVE PREPARATION

Preoperative preparation involves stopping smoking, hydration, chest physiotherapy, bronchodilators, antibiotics and possibly steroids. Instruction in the use of incentive spirometry and psychological reassurance are also important, in addition to information on possible methods of postoperative analgesia, such as patient-controlled analgesia. The possibility of proceeding to a thoracotomy should be discussed. Current medications, with the exception of insulin, are continued until the morning of surgery. Benzodiazepines are commonly used to produce anxiolysis and sedation.

MONITORING

The early thoracoscopies were relatively short procedures requiring only brief periods of one-lung ventilation, using basic monitoring. However, as thoracoscopy evolved and became more complex, the procedure has become more similar to thoracotomy in terms of length and duration of one-lung ventilation (OLV). Thus monitoring similar to that used for thoracotomy is routine. This includes ECG, pulse oximetry, arterial cannulation for invasive arterial pressure monitoring and blood-gas sampling. Temperature, peripheral nerve block and end-tidal carbon dioxide monitors should also be used. Procedures used to treat pericardial disease or pericardial tamponade may be augmented by transoesophageal echocardiography. However, there are currently no guidelines for additional monitoring requirements for thoracoscopy, Hartrey, Posskitt and Durkin[35] and Fredman, Oslfanger and Jedeikin[27] reviewed patients undergoing transthoracic endoscopic sympathectomy using one-lung anaesthesia with non-invasive monitoring, and described it as a safe and effective technique. However, their patients were relatively healthy, unlike many patients requiring thoracoscopy, thus highlighting the need to assess each patient individually.

CHOICE OF ANAESTHESIA

Thoracoscopy may be performed under local, regional or general anaesthesia, depending on the proposed procedure, the technical abilities of the anaesthetist and surgeon, and the patient's physical and psychological state. Local anaesthetic infiltration of the lateral thoracic wall and the parietal pleura is the simplest method of providing analgesia. Intercostal nerve or thoracic extradural blocks provide more complete analgesia, supplemented with ipsilateral stellate ganglion block to inhibit the cough reflex stimulated by manipulation of the hilum. Advantages of local techniques are the ability to have an awake, spontaneously breathing patient who is able to cough after operation and has good analgesia. Menzies and Charbonneau[55] showed that diagnostic thoracoscopy for pleural disease under sedation and local anaesthesia was a feasible and safe procedure. The spontaneously breathing patient with an open chest in the lateral decubitus position may have impaired gas exchange as a result of paradoxical respiration and mediastinal shift. It is therefore important to keep the surgical procedure short and simple and always administer supplementary oxygen. General anaesthesia is therefore far more appropriate for most modern thoracoscopies. Intermittent positive pressure ventilation reduces the changes associated with mediastinal shift and prevents paradoxical respiration. It also allows easier monitoring of ventilation. General anaesthesia for thoracoscopy is an indication for the placement of a double-lumen endobronchial tube allowing lung deflation, safe insertion of trocars and provides a better view of the operative side. The lung can be re-expanded under direct vision to assess air leaks or adhesions.

INDUCTION

The anaesthetic technique is tailored to the individual patient. Anaesthesia is induced with either thiopental, etomidate or propofol, and neuromuscular block is provided by vecuronium, atracurium or pancuronium, depending on the proposed length of the procedure. Anaesthesia is maintained with an inhalation agent or continuous infusion of propofol. Opioids can be given to provide analgesia and supplement anaesthesia. Regional and general anaesthesia may be combined to allow a lighter general anaesthetic to be given and to provide postoperative analgesia.

ONE-LUNG ANAESTHESIA

Intermittent positive pressure ventilation in the anaesthetized, paralysed patient with an open chest in the lateral decubitus position can overcome the problems of mediastinal shift and paradoxical respiration encountered in the awake patient. However, there may still be considerable ventilation–perfusion mismatch. Pulmonary blood flow continues to be governed by gravity and changes in resistance in the vasculature, particularly in the non-dependent lung. Ventilation to the dependent lung is reduced because of loss of the dependent lung volume with anaesthesia, compression by mediastinal and abdominal contents, and suboptimal positioning. In addition, poor mucociliary clearance and absorption atelectasis is caused by the increased fraction of inspired oxygen used during one-lung ventilation.

Several techniques are available to achieve one-lung ventilation. The most common uses a double-lumen endobronchial tube (DLT). Many anaesthetists prefer to use left-sided DLT because of the ease of placement and greater margin of safety. Misplacement of a right-sided DLT introduces the risk of inadequate ventilation to the right upper lobe. Fibreoptic bronchoscopy has revealed malpositioning in 48% of cases[72] even though the double-lumen tube was thought to be in the correct position based on clinical signs. When the position of the DLT is confirmed only on the basis of clinical signs, there may be intraoperative problems with either deflating the non-dependent lung or completely separating the two lungs in 25% of the cases.[65] Confirmation of correct position is by fibreoptic brochoscopy[6] after the initial intubation and again when turned into the lateral decubitus position. During one-lung ventilation any blood flow to the non-ventilated lung becomes part of the shunt flow. Consequently, for the same $F\text{I}_{O_2}$, haemodynamic and metabolic status, one-lung ventilation results in a much larger alveolar–arterial oxygen tension difference and lower Pa_{O_2} than two-lung ventilation.

One-lung ventilation has much less effect on Pa_{CO_2} than on Pa_{O_2}. The ventilated lung can eliminate enough carbon dioxide to compensate for the non-ventilated lung. However, it cannot take up enough oxygen because of the plateau at the top end of the oxygen–haemoglobin dissociation curve.

There are both passive and active mechanisms operating during one-lung ventilation that reduce blood flow to the non-dependent, non-ventilated lung. Passive mechanisms include gravity, surgical interference and the extent of pre-existing disease in the non-dependent lung. Hypoxic pulmonary vasoconstriction causes the most dramatic reduction in blood flow to the non-dependent lung by an active vasoconstrictor mechanism. The selective increase in pulmonary vascular resistance of the collapsed lung diverts blood flow towards the remaining ventilated lung.

MANAGEMENT OF ONE-LUNG ANAESTHESIA

One-lung ventilation carries a risk of hypoxaemia. It is therefore important to optimally manage ventilation. $F\text{I}_{O_2}$ should be increased to 0.5 or 1.0 if required to maintain arterial oxygen saturation (Sp_{O_2}) greater than 90%. The benefits of ventilating the dependent lung with 100% oxygen far exceed the theoretical risks of absorption atelectasis and oxygen toxicity. The dependent lung should be ventilated with a tidal volume of approximately 10 ml kg^{-1} with close monitoring of airway pressures. Ventilatory frequency is adjusted to maintain Pa_{CO_2} at 5.3 kPa (40 mm Hg). If there is a problem with ventilation, the correct position of the double-lumen endobronchial tube should be confirmed with the fibreoptic bronchoscope. If hypoxaemia persists, differential lung ventilation should be instituted. Continuous positive airway pressure (CPAP) maintains the patency of the non-dependent lung airways allowing some oxygen distension of the alveolar spaces involved with gas exchange. Because the volume of the ventilated dependent lung is often decreased during one-lung ventilation, many attempts have been made to improve oxygenation by selectively treating this lung with positive end-expiratory pressure (PEEP).

An accepted risk is that PEEP-induced increase in lung volume can cause compression of the intra-alveolar vessels of the small dependent lung and increase pulmonary vascular resistance. Blood flow may then be diverted from the ventilated to the non-ventilated lung, thereby increasing the shunt and decreasing Pa_{O_2}. If oxygenation does not improve with CPAP 5 cm H_2O delivered to the non-dependent lung, PEEP 5 cm H_2O is added to the dependent lung. These pressures can be increased sequentially in search for the maximum compliance and a minimum right-to-left shunt.[7] Resumption of two-lung ventilation is the quickest way to improve oxygenation.

Chest drains are inserted at the end of surgery and connected to underwater drainage systems. In all but the most frail patients, the trachea should be extubated at the end of the procedure and monitored closely in a high dependency unit.

COMPLICATIONS

Haemorrhage is a rare complication of thoracoscopy. Bleeding may be rapid and profuse. Therefore, a large bore venous cannula should be sited before operation. Blood should be available for rapid transfusion. Hypotension may result from cardiac arrythmias, pulmonary embolus or myocardial infarction. Perforation of organs is rare. The anaesthetist should be aware of potential damage to the heart, pericardium, lungs, oesophagus and the sympathetic chain. Occasionally surgeons insufflate the pleural cavity with carbon dioxide via a Verres' needle which increases the risk of perforation of organs and may result in arterial carbon dioxide embolism. Haemodynamic instability is reported by some not to be a problem if the volume of gas is limited to 2 litre and insufflated slowly. However, Hill and colleagues[39] studied haemodynamic changes with positive pressure insufflation of carbon dioxide during OLV in pigs. They demonstrated significant haemodynamic compromise at pressures of 5 mm Hg and greater. A capnothorax has been described in humans which has also demonstrated that there are consequent adverse haemodynamic changes.[69]

Complications related to OLV include hypoxia most commonly caused by malposition of the DLT. During long procedures fluid may collect in the lower lung, particularly if generous i.v. fluids have been given, which further impair gas exchange. Bronchial rupture after over inflation of the bronchial cuff of the DLT is also a rare complication.

When securing the patient in the lateral decubitus position, care must be taken to avoid any nerve injury and to ensure that there is enough room for respiratory excursion. Finally, if laser therapy is used, ventilation with 100% oxygen must be seriously considered as a potential fire hazard.

POSTOPERATIVE MANAGEMENT

Thoracoscopy patients are spared a great deal of postoperative pain and respiratory dysfunction, leading to reduced morbidity and shortened hospital stay. However, these patients still require concerted efforts to minimize complications. A variety of techniques can be used to help reduce postoperative pulmonary complications. Incentive spirometry is an ideal respiratory care manoeuvre. Ensuring the patient sits upright in bed and early ambulation augments the FRC and helps restore a favourable FRC–closing volume relationship thus preventing further atelectasis. Percussion and postural drainage aid in the mobilization of secretions and continuing administration of bronchodilating drugs or steroids that were given before operation is important in maintaining reactive airways quiescent.

Treatment of postoperative pain

Thoracoscopy results in much reduced postoperative pain compared with thoracotomy. Pleural drainage time is also less.[56] Local anaesthetic solutions are often infiltrated into the incisions and pleural cavity, although there is some doubt whether the latter is effective.[8] Post-thoracoscopy pain can be treated by systemic administration of opioid and potent non-steroidal anti-inflammatory drugs.

Parenterally administered analgesics are usually necessary to relieve pain related to chest drains. Patient-controlled analgesia is also an efficient method. Regional analgesia is usually unnecessary in patients who have undergone simple thoracoscopy procedures but provides superior pain relief when used. Extradural analgesia confers the most benefit as it treats both the chest drain and incisional pain, and this improves pulmonary function.

In summary, anaesthesia for surgical telescopic procedures of the thorax has become more refined. Each procedure has certain but different anaesthetic considerations with the one common denominator being that all could be followed by thoracotomy. All medical and nursing staff should be aware of this possibility and be prepared if required to proceed immediately.

SHORT COMMUNICATIONS

Comparison of intubating conditions after rocuronium or vecuronium when the timing of intubation is judged by clinical criteria

I. SMITH AND R. S. G. SAAD

Summary

The onset of action and intubating conditions after rocuronium 0.6 mg kg^{-1} or vecuronium 0.1 mg kg^{-1} were compared in a randomized, double-blind study when the timing of tracheal intubation was determined by clinical judgment alone. Times to laryngoscopy and completion of intubation were mean 89 (SD 20) s and 119 (28) s, respectively, in the rocuronium group compared with 110 (26) s and 142 (32) s in the vecuronium group (P<0.05 in both cases). Rocuronium also resulted in significantly better intubating conditions compared with vecuronium but with no significant reduction in the haemodynamic response to intubation. We found that onset of satisfactory intubating conditions after rocuronium was detected clinically, although even earlier intubation should be possible by careful timing or by neuromuscular monitoring. (*Br. J. Anaesth.* 1998; **80**: 235–237)

Keywords: neuromuscular block, vecuronium; neuromuscular block, rocuronium; intubation tracheal

Rocuronium is related to vecuronium, but has greater lipophilicity, decreased potency and a faster onset. Good-to-excellent tracheal intubating conditions have been reported[1] within 60–90 s of a 2 × ED$_{95}$ dose of rocuronium 0.6 mg kg^{-1}. In most studies, the timing of tracheal intubation is determined by neuromuscular monitoring or occurs at a predetermined time after administration of neuromuscular blocking drugs. In clinical practice, however, neuromuscular monitoring and accurate timing are rarely used, and many anaesthetists commence laryngoscopy based on the clinical "feel" of the patient. Therefore, we have compared intubating conditions after vecuronium or rocuronium when the timing of laryngoscopy was determined solely by the clinical judgment of an experienced anaesthetist.

Methods and results

After obtaining approval from the local research Ethics Committee and written informed consent, we studied 52 adults undergoing elective inpatient surgery requiring general anaesthesia and tracheal intubation. Patients with neuromuscular disorders, those receiving drugs which might interfere with neuromuscular function and those with anticipated difficult intubation (Mallampati class III or IV)[2] were excluded. Patients were allocated randomly to receive vecuronium 0.1 mg kg^{-1} or rocuronium 0.6 mg kg^{-1}, prepared by an anaesthetist not involved in the study, as a 6-ml solution containing vecuronium 10 mg (1.67 mg ml^{-1}) or rocuronium 60 mg (10 mg ml^{-1}).

Drug administration, airway management and tracheal intubation were the responsibility of an anaesthetist who did not know to which group the patient was allocated. Anaesthesia was induced with propofol 2–2.5 mg kg^{-1} and fentanyl 1 µg kg^{-1}, followed by assisted ventilation with 2% enflurane (inspired concentration) and 60% nitrous oxide in oxygen. After loss of consciousness, neuromuscular block was monitored by acceleromyography[3] with single twitch stimulation at supramaximal, square-wave impulses of 0.2 ms duration, 1 Hz, at the ulnar nerve using a TOF-Guard monitor (Organon Teknika). After calibration to a baseline twitch height of 100%, the display (and the moving thumb) were shielded from the view of the anaesthetist, who injected the neuromuscular blocking drug from the previously prepared syringe at a dose of 0.06 ml kg^{-1} (equivalent to vecuronium 0.1 mg kg^{-1} or rocuronium 0.6 mg kg^{-1}). The timing of laryngoscopy was judged by the ease of ventilation, and jaw and upper airway tone. Jaw tone was assessed by attempting to open the patient's mouth, while upper airway tone was determined by the amount of jaw support necessary to maintain a patent airway. Laryngoscopy was performed with the patient in a standardized position (one pillow) using a size 3 Macintosh laryngoscope blade. Times from administration of neuromuscular blocking drug to beginning laryngoscopy and completion of tracheal intubation, and corresponding values on the neuromuscular monitor were recorded by an assistant. The anaesthetist graded intubating conditions using the Krieg score,[4] ranging from 3 (best possible intubating conditions) to 12 (worst possible conditions). The view at laryngoscopy was also graded: 1=all of the larynx seen; 2=part of the vocal cords seen; 3= epiglottis only seen; 4=no structures identified.[5]

Data were analysed by the Statview statistical package using unpaired t test, chi-square tests and non-parametric tests as appropriate. In all cases P< 0.05 was considered significant.

Data from two patients were excluded because of technical problems with the neuromuscular monitor;

therefore there were 25 patients in each group. The groups were similar in age, weight, sex, ASA status, Mallampati class, anaesthetic induction dose and time from induction of anaesthesia until administration of neuromuscular blocking drug. In the rocuronium group, laryngoscopy was commenced and tracheal intubation was completed earlier and at a more profound degree of neuromuscular block than in the vecuronium group (table 1). The view at laryngoscopy did not differ significantly between the groups, although two patients in the rocuronium group were grade 3 compared with none in the vecuronium group (table 1). Tracheal intubation was successful at the first attempt in 19 (76%) patients after rocuronium and in 21 (84%) patients after vecuronium. The remaining intubations were completed at the second attempt, except for one patient in the vecuronium group who required three attempts. A bougie was used to facilitate tracheal intubation in four of 25 patients in the rocuronium group (because of anatomical problems) compared with none in the vecuronium group. Nevertheless, intubating conditions were significantly better and intubation scores were significantly lower in the rocuronium compared with the vecuronium group (fig. 1). There were no significant differences between the groups in haemodynamic response to laryngoscopy or in haemoglobin oxygen saturation before or after tracheal intubation.

Comment

This study has confirmed the faster onset of rocuronium compared with vecuronium and showed that this could be detected clinically, allowing earlier intubation without accurate timing or neuromuscular monitoring. Using clinical judgment alone, intubating conditions were excellent or good in all patients who received rocuronium, although the measured degree of neuromuscular block suggests that the technique was relatively insensitive, and tracheal intubation could probably have been completed earlier, especially as rocuronium may have a faster onset of action at the larynx than at the adductor pollicis.[6] In contrast, clinical signs underestimated the time required for adequate onset of vecuronium.

Clinical judgment is subjective and may vary between individuals. In our study, tracheal intubation was performed by two different anaesthetists (both authors) who used the same technique and attempted to apply the same criteria. Nevertheless, their judgment varied greatly, and one anaesthetist consistently started laryngoscopy and completed tracheal intubation earlier (in both groups) than the other anaesthetist. Both anaesthetists achieved shorter intubation times and lower intubation scores in the rocuronium compared with the vecuronium group. This suggests that while clinical judgment may vary between individuals, the faster onset of rocuronium can be detected consistently.

Despite improved intubating conditions in the rocuronium group, four patients required a bougie to facilitate tracheal intubation. Two of these patients were grade 3 at laryngoscopy, despite being classified as Mallampati class 1 at the preoperative assessment (although more extensive evaluation might have identified potential problems). A bougie was chosen, in preference to alternative manipulations, as it reduced the delay in completing intubation and, in grade 3 patients, lifted the epiglottis sufficiently to see the vocal cords (open in both patients) and complete the Krieg score. The low scores in these patients (5 and 6) suggest that anatomical factors, rather than inadequate relaxation, were responsible for the difficulty.

In summary, clinical judgment adequately predicted satisfactory tracheal intubating conditions after rocuronium, allowing intubation to be completed within an acceptable period of time, although this interval could probably have been shortened by neuromuscular monitoring. In contrast, clinical judgment underestimated the time required for adequate onset of action of vecuronium, resulting in less favourable intubating conditions. Improved intubating conditions had no effect on haemodynamic response or oxygen saturation.

Vecuronium-induced neuromuscular block during xenon or sevoflurane anaesthesia in humans

Y. NAKATA, T. GOTO AND S. MORITA

Summary

Twitch response using accelerometry and plasma concentrations of vecuronium and its metabolite were studied in 27 surgical patients during xenon or sevoflurane anaesthesia after administration of vecuronium 0.05 mg kg^{-1}. Anaesthesia was maintained using oxygen–xenon (MAC=71%) or oxygen–sevoflurane (MAC=2%) at an end-tidal concentration equal to 0.8 MAC (i.e. 57% xenon and 1.6% sevoflurane). Mean time from administration of vecuronium to 25% recovery of the first twitch of the train-of-four response was significantly shorter in the xenon group than in the sevoflurane group (12.9 (SD 2.5) min *vs* 19.4 (6.0) min, respectively). Plasma concentrations of vecuronium at 25% recovery were significantly higher during xenon than during sevoflurane anaesthesia (187 (49) ng ml^{-1} *vs* 136 (40) ng ml^{-1}, respectively), while those of 3-desacetylvecuronium were similar in both groups. (*Br. J. Anaesth.* 1998; **80**: 238–240)

Keywords: anaesthetics gases, xenon; anaesthetics volatile, sevoflurane; monitoring, neuromuscular block; neuromuscular block, vecuronium; neuromuscular block, measurement of response.

Xenon and sevoflurane are inhaled anaesthetics with a low blood-gas solubility coefficient which have been used in conjunction with neuromuscular blocking agents during clinical anaesthesia.[1] Potent inhalation anaesthetics variably influence the neuromuscular blocking effects of neuromuscular blocking agents, and sevoflurane has been evaluated in this respect.[2] However, the neuromuscular blocking effects of xenon have never been evaluated. To characterize the interaction between xenon and non-depolarizing neuromuscular blocking agents, we studied the onset and duration of vecuronium-induced neuromuscular block, and plasma concentrations of vecuronium and 3-desacetylvecuronium under equianaesthetic concentration of xenon and sevoflurane anaesthesia.

Methods and results

After obtaining approval from the Institutional Human Studies Committee of Teikyo University and informed consent, we studied 27 ASA I–II adult patients undergoing elective general, orthopaedic, gynaecological or ENT surgery. No patient had neuromuscular, renal or hepatic disorders or was receiving any medication that might alter neuromuscular transmission. Patients were allocated randomly to one of two groups; 12 patients received xenon and 15 received sevoflurane anaesthesia.[3]

No patient was premedicated. In the operating room, standard monitoring (electrocardiogram, pulse oximetry and non-invasive arterial pressure) was commenced. Arterial pressure was measured at 5-min intervals with a cuff positioned on the right arm. Lactated Ringer's solution was infused slowly via an i.v. cannula inserted in the left antecubital fossa. After induction of anaesthesia with fentanyl 0.5–1.0 μg kg^{-1} and propofol 2–6 mg kg^{-1}, the trachea was intubated without neuromuscular blocking agents. Anaesthesia was maintained with oxygen–xenon (MAC=71%[4]) or oxygen–sevoflurane (MAC =2%) at an end-tidal concentration equal to 0.8 MAC (i.e. 57% xenon and 1.6% sevoflurane). Xenon concentration was monitored continuously at the Y connector with an AZ720 Xenon Monitor (Anzai Medical, Tokyo, Japan) and sevoflurane with an Ultima (Datex, Helsinki, Finland). There is no report in the literature demonstrating intraoperative awareness during anaesthesia with approximately 60% xenon. Even 30% xenon is known to suppress the stress response to noxious stimuli because of its analgesic effects.[5] Thus the concentration of xenon used in this study was expected to provide an adequate level of anaesthesia. A low-flow technique was used for xenon anaesthesia. The lungs were ventilated mechanically to maintain end-tidal carbon dioxide concentration at 4.0–4.7 kPa (Datex Ultima, Helsinki, Finland). Core temperature was maintained at 35.5–37.0°C using warming blankets. The right radial artery was cannulated at the wrist with a 22-gauge cannula and flushed with heparin for blood sampling.

Neuromuscular block was monitored with an accelerometer (TOF-guard; Biometer International, Odense, Denmark). Both arms were extended and the hands were fixed in supination beside the patient with the left thumb allowed to move freely. An accelerometer was attached via silver–silver chloride electrodes over the position of the ulnar nerve at the left wrist. The supramaximal current was determined using the automatic set-up procedure of the TOF-guard. This uses a current of 1 Hz which tests initially the electrode connections at 20 mA and then increases the stimula-

tion to 60 mA. Twitch height is adjusted to 100% and the stimulation current is decreased automatically until twitch height starts to decrease. The current corresponding to this decrease is stored and the stimulation current returned to 60 mA. When the supramaximal stimulus had been determined, the stimulator continued to stimulate the ulnar nerve with a train-of-four (TOF) pattern at 15-s intervals. When the response to TOF stimulation was stable, the magnitude of the first twitch of the train was taken as control twitch height. The end-tidal anaesthetic concentration and twitch response were stable for 45 min before administration of vecuronium. All neuromuscular responses were based on the first twitch of the TOF (twitch response).

Approximately 60 min after induction of anaesthesia, vecuronium 0.05 mg kg^{-1} was given i.v. When the twitch response had recovered to 25%, 10 ml of blood were obtained via the arterial cannula for measurement of vecuronium concentration. Onset time was defined as the time from the beginning of administration of vecuronium to 90% depression of the first twitch of the TOF response. Duration of action was defined as the time from the beginning of administration of vecuronium to 25% recovery of the first twitch response. During the study, we monitored clinical signs of potential intraoperative wakefulness, such as lacrimation, sweating and tachycardia. Increases in arterial pressure of more than 20% of baseline were treated immediately with incremental doses of fentanyl 50 µg i.v. On the day after surgery, all the patients were asked if they recalled any perioperative event or felt pain or discomfort during the study.

Blood samples were centrifuged promptly and the plasma removed. Plasma was buffered with NaH_2PO_4, frozen and stored at −35°C for subsequent measurement of concentrations of vecuronium and 3-desacetylvecuronium using gas chromatography [6]. The assay has a sensitivity of 5 ng ml^{-1} and a coefficient of variance of 15% at 10 ng ml^{-1}.

All numerical data were analysed using unpaired *t* tests.[3] $P<0.05$ was considered statistically significant. All values are reported as mean (SD).

There were no significant differences between patient data or doses of propofol and fentanyl in the two groups. All patients achieved at least 90% twitch depression. Duration of action of vecuronium was 25% shorter in the xenon compared with the sevoflurane group (table 1). No patient in either group showed clinical signs of potential intraoperative wakefulness or recalled intraoperative events when interviewed after operation.

We obtained blood samples from 24 patients; we failed to obtain blood samples from three patients in the sevoflurane group because of our inability to cannulate the right radial artery. Plasma vecuronium concentrations were 40% higher during xenon anaesthesia at 25% recovery of the first twitch of the TOF.

Comment

Our findings on the duration of action of vecuronium 0.05 mg kg^{-1} are consistent with previous studies which showed that potent inhalation anaesthetics variably influence non-depolarizing neuromuscular blocking agents,[2] although no direct comparison had been made between xenon and sevoflurane. Our study demonstrated that xenon had a lesser effect on recovery from vecuronium-induced neuromuscular block than sevoflurane.

The similar onset times of vecuronium in the xenon and sevoflurane groups may appear to conflict with their different durations of action. Although the exact mechanism of this similarity was not determined in our study, small doses (0.8 MAC) of inhaled anaesthetics and the small sample sizes could explain the lack of difference in onset time between the two anaesthetic groups.

Plasma concentrations of vecuronium were 40% higher during xenon compared with sevoflurane anaesthesia at similar levels of recovery from block. Assuming that plasma concentrations of vecuronium and 3-desacetylvecuronium reflect those at the neuromuscular junction, this suggests that xenon produces a smaller neuromuscular blocking effect than sevoflurane. However, in our study vecuronium was administered as a bolus, not as a continuous infusion, in order to duplicate our clinical practice. This design did not achieve steady state plasma vecuronium concentrations and may be criticised because of the possible lack of equilibration between the plasma and neuromuscular junction. Therefore, plasma concentrations of vecuronium and 3-desacetylvecuronium in our study may not have reflected concentrations at the neuromuscular junction at that time. We provide only suggestive, but not conclusive, evidence that xenon has lesser pharmacodynamic effects than sevoflurane.

Current practice of local anaesthesia for routine ocular surgery

R. J. MAWER AND A. G. A. COOMBES

Summary

We surveyed the current practice of local anaesthesia for routine ocular surgery by consultant anaesthetists in the Wessex region using a postal questionnaire. Most consultants were in agreement concerning the type and technique of block, and monitoring to be used during local anaesthesia for ocular surgery. The issue of teaching for trainee anaesthetists produced a varied response. We found that a different level of perioperative preparation and monitoring was used from that recommended by the Joint Working Party on the subject in 1993. (*Br. J. Anaesth.* 1998; **80**: 241–242)

Keywords: anaesthetics local; surgery, ophthalmological; anaesthesia, audit

In March 1993, a Joint Working Party representing the Royal Colleges of Ophthalmology and Anaesthetists published recommendations for the perioperative management of patients undergoing ophthalmic surgery. Using a postal survey, we aimed to observe the extent to which some of these recommendations are now usual practice for consultant anaesthetists in charge of routine ophthalmic lists. We report the views on provision for teaching of local eye blocks to anaesthetic trainees, the type of blocks performed, precautions taken and complications encountered during the time of insertion of the block and in the perioperative period.

Methods and results

Anaesthetic secretaries supplied the names of consultant anaesthetists who regularly attended ophthalmic lists in the Wessex region. A one-page questionnaire, covering letter and self-addressed envelope were sent to 37 consultant anaesthetists. The questionnaire included tick-box responses to questions on who performed local eye blocks, indications for the block and techniques used for the block. We enquired which preoperative investigations were usually performed, if i.v. access was established, and what monitoring was used routinely before the block and in the peroperative period. Details of complications which had been encountered were requested, as were teaching methods available for trainees.

The response rate to the postal survey was 84%. Each consultant attended an average of 1.3 lists per week. The average number of patients per list was 4.4, 61% of whom received local anaesthesia for surgery. Eighteen consultant anaesthetists (61%) gave eye blocks, as did 35% of their trainees. Twenty consultants felt that the most important indication for performing a local block was a serious coexisting medical condition, while four believed that day-case surgery and four that surgical preference were most important. Twenty-three responders performed peribulbar blocks with or without topical anaesthesia. Three consultants performed retrobulbar blocks and five performed both peribulbar and retrobulbar blocks.

Axial length was considered before performing a block by 28 responders (90%) and the position of straight gaze was used by all consultants performing retrobulbar blocks. All consultants used 25-gauge needles. Twelve consultants performing peribulbar blocks used 25-mm, three used 16-mm and one used 38-mm length needles. Two consultants performing retrobulbar blocks used 25-mm and three 38-mm length needles. Two consultants used bupivacaine alone and five used lidocaine with bupivacaine. The remainder used a combination of lidocaine, bupivacaine and hyaluronidase.

Monitoring was instituted before performing a local block by 16 consultants (52%). In the peroperative period, pulse oximetry was used by 31 (97%), ECG by 18 (58%) and indirect arterial pressure monitoring by 10 (32%) consultants. Sixteen consultants (52%) established i.v. access as routine. Twelve of the consultants (39%) requested that patients had the same preoperative investigations as for a general anaesthetic, including full blood count, electrolyte concentrations, ECG and chest x-ray, if appropriate, and all had resuscitation equipment available (table 1).

Nine consultants had encountered retrobulbar haemorrhage as a complication of local eye blocks, one had witnessed respiratory arrest and three had observed the oculocardiac reflex as a result of a block.

Trainees were allowed to perform blocks by 35% of the consultants. Forty-two percent of trainees had been taught by an anaesthetist, 16% had been taught by an ophthalmic surgeon and 10% were taught by both. It was not known who taught the remaining 32% of the trainees performing blocks. Fourteen consultants (45%) felt that there was no need for a specific teaching programme for their juniors; four reported that there was a teaching programme in

operation and 10 felt that a programme would be worthwhile.

Comment

The average age of patients on ophthalmic lists in the study by Fisher and Cunningham was 75 yr,[2] of whom 84% suffered from significant systemic illness. Silent myocardial ischaemia in the elderly is well documented, as are side effects relating to multiple drug therapy. It is for these reasons that the Working Party recommended that all patients should be assessed fully before operation. In this study, patients of only 12 consultants (39%) were prepared in the same way as for a general anaesthetic.

Anaesthetists have been implicated in causing a higher rate of complications when performing local anaesthetic blocks than ophthalmic surgeons.[3] Previous reports have indicated that the overall incidence of retrobulbar haemorrhage is approximately 1%. This was the complication most frequently encountered by consultant anaesthetists who performed blocks in this study and by their ophthalmological colleagues who also performed blocks. Unfortunately, we did not establish the frequency with which this or other complications occurred. The consultant who had witnessed respiratory arrest did so once in a series of 2000 patients.

Some studies have disputed that the oculocardiac reflex can be initiated by insertion of a block.[4] In this survey, three consultants reported this reflex occurring while a block was being performed. This may also reflect under-reporting as only 52% of consultants used perioperative monitoring.

The Working Party recommendations state that i.v. access should be mandatory before any anaesthetic intervention but this was standard practice for only 52% of anaesthetists surveyed. The results of this study showed that a different level of perioperative preparation and monitoring was used in practice from that recommended in 1993.[1] The CEPOD report stresses "that practice amongst anaesthetists is not stereotyped but the fact that more than 90% of practitioners do follow certain patterns supports the notion that standards of practice could now be written".[5]

The question must be raised whether peer group practice should be accepted as the standard; the alternative would be to force a change in current practice. A change in practice in dental anaesthesia followed the Poswillo report when the recommendations were based on objective information concerning the risk of arrhythmia. The risks of monitoring are negligible. Surely the institution of ECG monitoring and i.v. access before insertion of the block should remain as a guideline and be accepted as standard practice?

This study showed that despite the absence of formal teaching programmes, most consultants seemed well aware of the potential complications of siting a local eye block, in addition to the current recommendations to reduce the incidence of side effects. The methods of performing blocks and perioperative monitoring of patients were similar throughout the region.

If the practices and opinions of Wessex anaesthetists are representative of national practices, the question arises if recommended guidelines should be changed to fit with current practices. Alternatively, the recommendations could remain and force a change in anaesthetic monitoring for routine ocular surgery.

This survey should be extended nationally. An extended survey questionnaire should be altered to allow recording of the frequency of complications encountered and the opinions of trainee anaesthetists on the best methods and adequacy of training available for regional eye blocks.

Desflurane maintains intraocular pressure at an equivalent level to isoflurane and propofol during unstressed non-ophthalmic surgery

S. Sator, E. Wildling, C. Schabernig, J. Akramian, E. Zulus and M. Winkler

Summary

We have investigated the effects of desflurane compared with isoflurane and propofol on intraocular pressure (IOP) in 48 ASA I–II patients undergoing elective non-ophthalmic surgery. Anaesthesia was induced with thiopental 3–5 mg kg^{-1}, fentanyl 2–4 μg kg^{-1} and vecuronium 0.1 mg kg^{-1}. Patients were allocated randomly to receive propofol (n=16) 4–8 mg kg^{-1} h^{-1}, isoflurane (n= 16) or desflurane (n=16) for maintenance of anaesthesia. Fentanyl was added if necessary. The lungs were ventilated with 70% nitrous oxide in oxygen. Arterial pressure, electrocardiography, heart rate and end-tidal carbon dioxide were measured throughout anaesthesia. IOP was measured before surgery, during maintenance and after emergence from anaesthesia with applanation tonometry by an ophthalmologist blinded to the anaesthetic technique. There was a significant decrease in IOP after induction of anaesthesia which did not differ between groups. Desflurane maintained IOP at an equivalent level to isoflurane and propofol. (*Br. J. Anaesth.* 1998; **80**: 243–244)

Keywords: anaesthetics volatile, desflurane; anaesthetics volatile, isoflurane; anaesthetics i.v., propofol; eye, intraocular pressure

One aim of anaesthetic management during ophthalmic surgery is to provide good control of intraocular pressure (IOP). An increase in IOP may be catastrophic in patients with glaucoma or a penetrating open-eye injury. Anaesthesia in these patients must prevent an increase in IOP and provide a "soft" eye which is suitable for surgery and free of haemorrhage, particularly expulsive choroidal haemorrhage.

IOP is determined by the rate of production of aqueous humour and vitreous volume, choroidal blood volume, scleral rigidity, orbicularis oculi muscle tension and external pressure.[1] Many studies have examined the effects of anaesthetics and related drugs on IOP. Inhalation anaesthetics such as halothane and isoflurane decrease IOP by lowering the formation rate of aqueous humour and increasing the trabecular outflow facility.[2 3] The i.v. hypnotic agents propofol and thiopental also decrease IOP and have been demonstrated to attenuate the increase in IOP in response to laryngoscopy and intubation.[4]

Desflurane is a volatile anaesthetic with a low blood-gas solubility coefficient. Recovery from anaesthesia with desflurane is more rapid than with other potent inhalation anaesthetic agents and comparable with propofol. Because of its irritant properties on the airway, desflurane is not suitable for inhalation induction of anaesthesia in ophthalmic patients, but it may be an ideal maintenance anaesthetic. In dogs, desflurane (7.0% expired) was associated with a baseline IOP of 11.3 (SD 3.8) mm Hg[5]: normal IOP is approximately 15 mm Hg, with a "normal" range of approximately 10–20 mm Hg.

There have been no studies on the effects of desflurane on IOP in humans. We performed a randomized, prospective, single-blind study to compare the effects of desflurane, isoflurane and propofol on IOP in patients undergoing elective non-ophthalmic surgery.

Methods and results

After obtaining approval from the Ethics Committee of Vienna General Hospital, we studied 48 patients undergoing elective non-ophthalmic surgery. Inclusion criteria were age 16–60 yr, ASA I or II, no known allergies or adverse reactions to any of the anaesthetic agents used in the study, and no pre-existing ophthalmic disease. Before surgery, patients were allocated randomly to one of three groups: propofol (n=16), isoflurane (n=16) or desflurane (n=16). All patients were premedicated with midazolam 7.5 mg, 1 h before surgery. Anaesthesia was induced with fentanyl 2–4 μg kg^{-1}, thiopental 3–5 mg kg^{-1} and vecuronium 0.1 mg kg^{-1}. Ventilation was adjusted to maintain end-tidal carbon dioxide partial pressure at 4.3–4.6 kPa. Anaesthesia was maintained with continuous infusion of propofol 4–8 mg kg^{-1} h^{-1} (n=16) or 1 MAC of isoflurane or desflurane. The lungs were ventilated with 70% nitrous oxide in oxygen. Arterial pressure, electrocardiography, heart rate, oxygen saturation, end-tidal carbon dioxide concentration and nasopharyngeal temperature were measured throughout anaesthesia. IOP was obtained by a hand-held applanation tonometer (Perkins). Patients were positioned supine for examination. All measurements were made by one ophthalmologist blinded to the

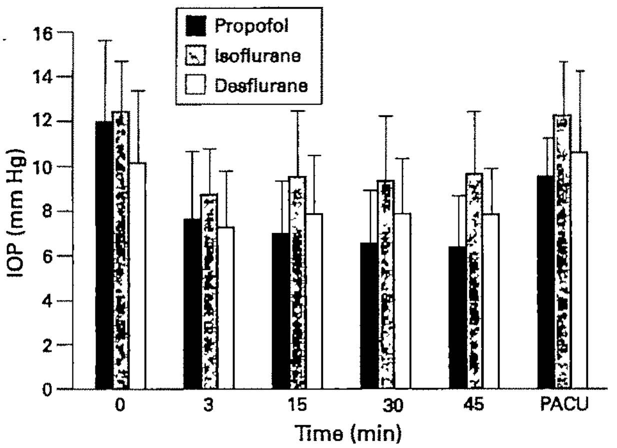

Figure 1 Mean (SD) intraocular pressure (IOP) in the propofol, isoflurane and desflurane groups. PACU=Post-anaesthesia care unit.

anaesthetic technique. IOP was measured before induction of anaesthesia, immediately before intubation, 1, 3, 5 and 10 min after intubation, every 15 min during anaesthesia and at least 1 min after extubation. A final measurement was performed in the recovery room.

One-way ANOVA with Scheffé's *post hoc* test was used to compare baseline data. ANOVA for repeated measures and paired *t* tests were used to assess differences within groups. Correlations were performed using Pearson's correlation coefficient. All data are presented as mean (SD). $P<0.05$ was considered significant.

All patients were evaluated and were comparable in age, weight, sex and duration of operation. Baseline values of mean arterial pressure (MAP), heart rate and IOP were similar between groups. After induction of anaesthesia, IOP decreased significantly 1 min after the end of induction (propofol group, $P<0.05$; isoflurane and desflurane groups, $P<0.01$). During maintenance of anaesthesia, there were no significant changes in IOP over time in any group (fig. 1). In the recovery room, IOP returned to baseline in the desflurane and isoflurane groups, but remained significantly lower in the propofol group ($P<0.01$). MAP and heart rate decreased significantly from baseline (both $P<0.01$) during anaesthesia but increased towards baseline in the recovery room. There were no significant differences in MAP or heart rate between groups. No correlation was found between MAP, heart rate and IOP values.

Comment

The results of this study demonstrated that induction of anaesthesia significantly decreased IOP. Maintenance of anaesthesia with desflurane sustained a low IOP at a level equivalent to that of isoflurane and propofol.

Many factors (in addition to glaucoma) influence IOP, such as genetic status, age, refractive error and race. In addition, IOP is dependent on PEEP ventilation, $P\mathrm{A}'_{\mathrm{O_2}}$ and $P\mathrm{A}'_{\mathrm{CO_2}}$. Any acute increase in intra-abdominal or intrathoracic pressure, not infrequently observed during extubation, may increase IOP. Particular attention must be paid to induction of and emergence from anaesthesia as both mechanical and pharmacological stresses have an amplifying effect on IOP. Most anaesthetic and hypnotic agents, including volatile anaesthetics, barbiturates, opioids, neuroleptics and benzodiazepines decrease IOP in proportion to the depth of anaesthesia. Jantzen emphasized the importance of anaesthetic drugs for general anaesthesia in ophthalmic surgery.[6] He reported that i.v. anaesthetics and volatile agents reduce IOP, with the possible exception of ketamine.

There have been no studies assessing the influence of desflurane on IOP in humans. Artru demonstrated the influence of desflurane and halothane anaesthesia on IOP in dogs.[5] Both halothane and desflurane decreased IOP by approximately 7 mm Hg from baseline values in unanaesthetized dogs, with no difference between groups.

The results of our study indicate that desflurane, in common with isoflurane and propofol, maintained low IOP values during anaesthesia in patients undergoing non-ophthalmic surgery. The decrease in IOP after induction of anaesthesia was sustained if maintenance was provided by desflurane, isoflurane or propofol. In all groups, IOP increased towards baseline values after emergence from anaesthesia. Interestingly, IOP values remained significantly lower compared with baseline in the propofol group. We conclude that desflurane was as safe as isoflurane and propofol for maintenance of anaesthesia. The sustained low IOP after propofol anaesthesia may be beneficial in patients at risk and remains to be evaluated.

Intraperitoneal bupivacaine or lidocaine does not provide analgesia after total abdominal hysterectomy

P. B. ALI, B. R. COTTON, K. M. WILLIAMSON AND G. SMITH

Summary

We have compared pain scores at rest and on standardized movement, and morphine consumption using patient-controlled analgesia in 60 patients who had undergone total abdominal hysterectomy. Patients were allocated randomly to one of three groups: in the saline group, 0.9% sodium chloride 50 ml was administered into the pelvic cavity before closure of the peritoneum; in the second group, the solution administered was 20 ml of 0.5% bupivacaine solution with epinephrine 1:200 000 diluted with saline to a final volume of 50 ml; in the third group, the solution used was 20 mg of 2% lidocaine with epinephrine 1:200 000 diluted with saline to a final volume of 50 ml. We found that there was no significant difference between the three groups in visual analogue pain scores at 8, 12, 36 or 48 h after operation at rest or on movement, and no significant difference in sedation or dose of antiemetic administered. Mean morphine consumption in the first 24 h was 54.6 (SEM 5.9) mg in the saline group, 55.5 (6.4) mg in the bupivacaine group and 52.5 (5.3) mg in the lidocaine group. In the second 24 h, morphine consumption was 34.9 (6.6) mg, 28.1 (3.5) mg and 28.0 (3.5) mg in the three groups, respectively. We conclude that i.p. administration of local anaesthetic solution into the pelvic cavity did not confer appreciable analgesia in patients undergoing abdominal hysterectomy. (*Br. J. Anaesth.* 1998; **80**: 245–247)

Keywords: anaesthetics local, lidocaine; anaesthetics local, bupivacaine; analgesia, postoperative; surgery, gynaecological

Recently, we conducted a preliminary study[1] comparing saline with a relatively modest dose of lidocaine (200 mg) administered into the peritoneal cavity after total abdominal hysterectomy to determine if the resultant plasma concentrations of local anaesthetic were within a safe range and whether or not there was any appreciable analgesic effect. We found that there was a small but statistically significant difference in pain scores at rest between the saline and lidocaine groups but no significant difference in morphine consumption by patient-controlled analgesia (PCA) or pain scores during movement; plasma concentrations of lidocaine were below the toxic range. That study also provided pilot data on which to base a power analysis for this study, which was designed to see if a larger dose of lidocaine or a longer acting local anaesthetic (bupivacaine) produced analgesia in this situation.

Methods and results

After obtaining approval from the Leicestershire Ethics Committee and written informed consent, we studied 60 patients undergoing total abdominal hysterectomy. All patients were aged 20–60 yr, ASA I or II, not undergoing surgery for malignancy, and were scheduled for surgery undertaken via a standard Pfannenstiel incision. Patients were excluded if they had hepatic, vascular or cardiac disease, or allergy to local anaesthetic agents.

The anaesthetic technique was standardized and comprised premedication with temazepam 10 mg, 1–2 h before operation. Anaesthesia was induced with a sleep dose of propofol 150–200 mg, followed by vecuronium 0.1 mg kg^{-1}. After tracheal intubation the lungs were ventilated artificially with a mixture of 1.5–2% enflurane and 66% nitrous oxide in oxygen. Shortly after induction of anaesthesia, morphine 10 mg was administered as a standard bolus to all patients, together with prochlorperazine 12.5 mg.

After removal of the uterus, the anaesthetist opened a sealed envelope indicating to which group the patient was allocated; each patient's number was drawn from a list of computer-generated random numbers. In the saline group, the anaesthetist prepared a syringe containing 50 ml of sterile 0.9% sodium chloride, in the bupivacaine group 50 ml of 0.2% bupivacaine with epinephrine (1:500 000 dilution, prepared by adding 30 ml of saline to 20 ml of 0.5% bupivacaine containing epinephrine 1:200 000) and in the lidocaine group 50 ml of 0.8% lidocaine with epinephrine (1:500 000 dilution, prepared by adding 30 ml of saline to 20 ml of 2% lidocaine containing epinephrine 1:200 000). One of these three solutions was administered into the pelvic cavity before closure of the peritoneum and anterior abdominal wall. The hysterectomy was carried out using a standard technique; the peritoneum over the vault of the vagina was not closed and the solution was instilled into the pelvic cavity after haemostasis

had been secured, when all packs had been removed from the peritoneal cavity and the patient was placed in the supine horizontal position.

The patients, surgeons, theatre nursing staff, pain sister responsible for conducting observations in the postoperative period and the ward nursing staff were unaware of the groups to which patients were allocated.

In the recovery room, patients were provided with patient-controlled analgesia equipment (Abbott PCA II); this was programmed to deliver morphine in 1-mg boluses with a 5-min lockout period, the use of which had been explained to the patient at the preoperative interview. In our unit, it is policy to allow the pain sister to administer bolus doses of morphine up to 5 mg i.v. in the recovery unit in order to provide optimum analgesia before the patient commences self-administration of morphine; if 5 mg is inadequate, the anaesthetist is called to provide optimum analgesia before the patient is returned to the ward.

In the postoperative period, pain scores were recorded by the patient using a linear analogue score (10-cm scale: 0=no pain, 100=maximum pain conceivable) at 8, 12, 24, 36 and 48 h at rest and on movement, which was standardized as elevation from the horizontal to the supine position. Sedation scores were also recorded at 8- and 12-h intervals using a linear analogue score (0=wide awake, 100=drowsy to the point of sleeping).

From a power analysis conducted on our preliminary study, we calculated that this study had a 90% power to detect a two-sided significant difference at the 5% level of 20 mm in pain scores, 20 mg in morphine consumption in the first 24 h and a 31-mg difference in morphine consumption in 48 h.

Data were analysed using SPSS on an IBM-compatible PC. Data were initially subjected to a Komolgorov–Smirnov goodness-of-fit test and if found to be distributed normally, were then analysed using MANOVA with Scheffé and Bonferroni *post hoc* tests. Non-normally distributed data were analysed by Kruskal–Wallis tests.

The three groups were comparable in age and weight, and there were no significant differences in any variable between the three groups. In particular, there was no significant difference in morphine consumption in the first or second 24 h after operation and no significant difference in pain scores at rest or during movement (table 1). The dose of morphine given in each group in the first 24 h includes any bolus given in the recovery room but not during anaesthesia. Approximately 20% of all patients were given a bolus dose in the recovery room and there was no difference between groups in the numbers of patients receiving these boluses.

Comment

Recently, there has been interest in the use of peritoneal administration of local anaesthetic as a means of controlling pain after surgery. For laparoscopic sterilization, local anaesthetic may be injected into the mesentery of the fallopian tube, but in 1991 Narchi, Benhamou and Fernandez described the use of large volumes of dilute local anaesthetic administered into the peritoneal cavity for treatment of pain after laparoscopy. Using the standard maximum recommended doses of both lidocaine and bupivacaine with epinephrine, these workers demonstrated significant reductions in mean pain scores in the local anaesthetic groups from 8 to 24 h after surgery compared with a control group in which saline was administered into the intraperitoneal cavity.[2 3] A subsequent study revealed that plasma concentrations of lidocaine and bupivacaine after i.p. instillation of quite large doses of local anaesthetic did not approach toxic plasma concentrations.[4] Subsequently, it was shown that after laparoscopic cholecystectomy, pain was reduced after administration of 20 ml of 0.25% bupivacaine into the region of the gall bladder during surgery; although plasma concentrations of local anaesthetic were not measured, no patient exhibited clinical signs of toxicity.[5]

Recently, we undertook a preliminary study on i.p. installation of local anaesthetic after total abdominal hysterectomy, partly to determine the rate of absorption of lidocaine from the peritoneal cavity and partly to provide the basis of a power analysis for conducting this study.[1] In that preliminary study, we found that plasma concentrations of lidocaine after an i.p. dose of 200 mg did not approach toxic concentrations, thus reassuring us that it was reasonable to undertake the present study using lidocaine 400 mg.

We found that there was no significant difference in pain scores or morphine consumption for 48 h after operation in patients given lidocaine 400 mg, bupivacaine 100 mg or saline into the peritoneal cavity after total abdominal hysterectomy. This suggests that the difference in pain scores at rest found in our preliminary study was probably a chance observation. Indeed, that finding of a 13-mm difference in pain scores at rest at 24 h and 11 mm at 48 h was not accompanied by any difference in pain scores on movement. There was also no difference in morphine consumption between the lidocaine and saline groups.

The few studies on the use of i.p. administration of local anaesthetic in minor gynaecological surgery (laparoscopy) seem to have found consistently that the technique produced analgesia.[2,3,5] However, with major intra-abdominal surgery, the results are conflicting. Only two groups have claimed benefit for i.p. local anaesthetic after laparoscopic cholecystectomy[5,6] but a more substantial study by Joris and co-workers[7] failed to obtain any effect of i.p. bupivacaine on pain after laparoscopic cholecystectomy, despite the fact that visceral pain was demonstrated to account for most of the pain after this procedure. On the basis of both the present and our previous preliminary study, we also conclude that i.p. administration of local anaesthesia fails to confer appreciable analgesia in patients undergoing major gynaecological abdominal surgery.

Prevention of postoperative nausea and vomiting in female patients during menstruation: comparison of droperidol, metoclopramide and granisetron

Y. FUJII, H. TOYOOKA AND H. TANAKA

Summary

The incidence of postoperative nausea and vomiting (PONV) is high in women during menstruation. We have compared the efficacy of droperidol, metoclopramide and granisetron in the prevention of PONV in female patients during menstruation undergoing major gynaecological surgery. In a randomized, double-blind study, 120 patients received droperidol 25 µg kg^{-1}, metoclopramide 0.2 mg kg^{-1} or granisetron 40 µg kg^{-1} (*n*=40 in each group) i.v. immediately before induction of anaesthesia. A standard general anaesthetic technique and postoperative analgesia were used throughout. There was a complete response, defined as no PONV and no administration of rescue medication, during the 24-h observation period in 45% of patients in the droperidol group, 38% in the metoclopramide group and 70% in the granisetron group (P= 0.021 *vs* droperidol, P=0.003 *vs* metoclopramide). There was no difference in the incidence of adverse events between groups. We conclude that the prophylactic antiemetic efficacy of granisetron was superior to that of droperidol or metoclopramide for prevention of PONV in women during menstruation. (*Br. J. Anaesth.* 1998; **80**: 248–249)

Keywords: vomiting, nausea; vomiting, nausea, patient factors; vomiting, antiemetics, droperidol; vomiting, antiemetics, metoclopramide; vomiting, antiemetics, granisetron

Postoperative nausea and vomiting (PONV) are common and distressing symptoms in women after major gynaecological surgery performed under general anaesthesia. The aetiology of PONV after gynaecological surgery is multifactorial and includes age, obesity, history of motion sickness, previous postoperative emesis, type of surgery, anaesthetic technique and postoperative pain.[1] It has been reported that the incidence of PONV varies according to the phase of the menstrual cycle and a high incidence is associated with menstruation.[2] We have recently demonstrated that granisetron, a selective 5-hydroxytryptamine type-3 (5-HT$_3$) receptor antagonist, reduces the incidence of PONV in female patients during menstruation.[3] This study was designed to compare the efficacy of droperidol, metoclopramide and granisetron in the prevention of PONV in women during menstruation after major gynaecological surgery.

Methods and results

After obtaining approval from the Institutional Review Board and informed consent, we studied 120 ASA I or II women, aged 21–46 yr, during menstruation. The latter was elicited during routine enquiring. Patients who had gastrointestinal diseases and those who had received an antiemetic within 24 h before surgery were excluded.

Patients were allocated randomly to receive one of three treatment regimens: droperidol 25 µg kg^{-1}, metoclopramide 0.2 mg kg^{-1} or granisetron 40 µg kg^{-1} administered i.v. immediately before induction of anaesthesia.

Patients received no premedication. An extradural catheter was inserted at the L2–3 or L3–4 interspace and advanced into the extradural space. Anaesthesia was induced with thiopental 5 mg kg^{-1} i.v., and vecuronium 0.2 mg kg^{-1} i.v. was used to facilitate tracheal intubation. Anaesthesia was maintained with 1.0–3.0% (inspired concentration) isoflurane and 66% nitrous oxide in oxygen. Ventilation was controlled mechanically and adjusted to maintain PE'_{CO_2} at 4.6–5.2 kPa. A nasogastric tube was inserted and suction applied to empty the stomach of air and other contents. When haemodynamic variables were stable, 1.5% lidocaine 10–15 ml were injected via the extradural catheter. Neuromuscular block was produced with vecuronium as required. At cessation of surgery, atropine 0.02 mg kg^{-1} i.v. and neostigmine 0.04 mg kg^{-1} i.v. were administered for antagonism of neuromuscular block, and the trachea was extubated. After tracheal extubation, the nasogastric tube was suctioned and removed. If two or more episodes of vomiting occurred during the first 24 h after anaesthesia, another rescue antiemetic was given. Postoperative analgesia was provided with a mixture of 0.25% bupivacaine 40 ml and morphine 0.1 mg kg^{-1}. Patients in all groups were also allowed to receive indomethacin for intolerable pain.

Complete response, defined as no PONV (nausea, retching and vomiting) and no rescue antiemetic

medication during the first 24 h after anaesthesia, was recorded by nursing staff without knowledge of which antiemetic the patient had received.

Statistical analyses of the data between groups were performed by ANOVA with Bonferroni correction for multiple comparison, chi-square test or Fisher's exact exact probability test, where appropriate. $P<0.05$ was considered significant. All values are expressed as mean (SD) or number (%). We set $\alpha=0.05$ and $\beta=0.8$, and used a large magnitude of effect (effect size 0.8) to estimate a sufficient sample size. The analysis showed that 40 patients per treatment group would be sufficient.

Patient characteristics and surgical procedures did not differ between groups. During the 24-h observation period, the incidence of complete response (no PONV, no rescue) was 45% in the droperidol group, 38% in the metoclopramide group and 70% in the granisetron group (P=0.021 *vs* droperidol; P= 0.003 *vs* metoclopramide). Six patients who had received droperidol and seven who had received metoclopramide received a rescue antiemetic, compared with none who had received granisetron ($P<0.05$) (table 1). There were no adverse effects in any group.

Comment

In previous studies the incidence of PONV in female patients undergoing gynaecologic laparoscopic surgery increased during the first 8 days of their menstrual cycle (menstruation). We also demonstrated that the incidence of PONV in patients receiving placebo during menstruation was higher than that during non-menstruation.[3] The precise mechanism of an apparent increase in the incidence of PONV during the menstrual period is not known. However, it has been postulated that changing concentrations of follicle-stimulating hormone (FSH) or oestrogen, or both, may sensitize the chemoreceptive trigger zone or the vomiting centre, or both.[2] Several factors, including age, sex, obesity, history of motion sickness or previous PONV, operative procedure, anaesthetic technique and postoperative pain are also considered to increase the incidence of PONV after general anaesthesia for elective surgery.[1] In this study, however, the groups were similar in patient characteristics, surgical procedures, anaesthetic administered and analgesics used after operation. Therefore, the difference in the incidence of PONV between the groups was attributable to the differences in the agents administered.

Granisetron has already been shown to be an effective treatment for cisplatin-induced nausea and vomiting.[4] We have demonstrated that granisetron 40 μg kg^{-1} was effective in preventing PONV after gynaecological surgery,[5] and have recently demonstrated that it reduces the incidence of PONV regardless of the menstrual cycle.[2] This study also demonstrated that the incidence of complete response (no PONV, no rescue) in female patients during menstruation who had received granisetron was remarkably high and significantly better than droperidol 25 μg kg^{-1} or metoclopramide 0.2 mg kg^{-1}.

Effects of isoflurane–nitrous oxide anaesthesia on insulin secretion in female patients

J. P. DESBOROUGH, M. G. KNOWLES AND G. M. HALL

Summary

In vitro studies suggest that volatile anaesthetic agents may directly inhibit insulin secretion. It is unclear if supplementation of anaesthesia with isoflurane impairs insulin secretion. We performed a 5-g i.v. glucose tolerance test in 21 patients before and during anaesthesia which was maintained with either 1 or 2 MAC of isoflurane in nitrous oxide, or no volatile agent. The study was carried out before surgery to avoid the influence of hormonal responses to trauma. A significant glycaemic response occurred during both i.v. glucose tolerance tests in all three groups of patients. Serum insulin concentrations were measured and the acute increase in insulin concentration at 3 min and area under the curve for 15 min were calculated. Both variables decreased significantly in all three groups during the tests performed under anaesthesia compared with tests carried out before anaesthesia. (*Br. J. Anaesth.* 1998; **80**: 250–252)

Keywords: hormones, insulin; sympathetic nervous system, catecholamines; metabolism, glucose; metabolism, insulin; anaesthetics volatile, isoflurane

Surgical trauma results in a hormonal and metabolic response, which includes an increase in the concentrations of catabolic hormones and hyperglycaemia. *In vitro* experiments showed a significant inhibitory effect of volatile anaesthetic agents on insulin secretion from rat pancreatic islets.[1 2] Direct impairment of insulin release in humans by these agents may augment the glycaemic response to catabolic hormone secretion found in the perioperative period.

There are few clinical studies on the effects of inhalation anaesthesia on insulin secretion. Therefore, we have studied the insulin response to a 5-g i.v. glucose tolerance test (ivgtt) in healthy patients, both awake and during anaesthesia with 1 or 2 MAC of isoflurane in nitrous oxide, or an anaesthetic without a volatile agent, to determine if there was a specific inhibitory effect of isoflurane on insulin secretion.

Methods and results

The study was approved by the local Hospital Research Ethics Committee. Patients were undergoing elective tubal surgery for infertility. Any subject known to have polycystic ovarian disease, or metabolic or endocrine disorder, or receiving drugs known to alter hormone secretion and metabolism was excluded. All patients gave written, informed consent to the study.

Patients fasted overnight and the studies started in the morning. Premedication with morphine 10 mg and hyoscine 0.4 mg i.m. was given immediately before transfer from the ward.

Two control blood samples were obtained from a central venous catheter and, after 5 min, 50% glucose 10 ml was given i.v. as a bolus into the contralateral arm. Blood samples were obtained after 3, 4, 5, 7, 10 and 15 min. At the end of the awake ivgtt, after the 15-min sample, the patient rested until 60 min.

On completion of the first ivgtt, sealed envelopes were used to allocate patients randomly to receive 0, 1 or 2 MAC of isoflurane in 70% nitrous oxide after induction of anaesthesia. Fentanyl 2 μg kg^{-1} i.v. was given and anaesthesia was induced with thiopental. The trachea was intubated after vecuronium 0.1 mg kg^{-1} and the lungs were ventilated with 70% nitrous oxide in oxygen and isoflurane, as determined by study allocation. Continuous monitoring of partial pressure of expired carbon dioxide and of inspired and expired isoflurane was undertaken and expired carbon dioxide maintained at 4.5–5.0 kPa. In those patients allocated to receive 1 or 2 MAC of isoflurane, the designated partial pressure was achieved rapidly by adjusting the inspired isoflurane concentration (5–10 min after intubation).

Blood samples were collected immediately after induction of anaesthesia and intubation, and 10 min after steady end-tidal isoflurane values at the required MAC were achieved. A similar interval was allowed in patients allocated to the 0 MAC group before collection of another sample. The ivgtt was then repeated during anaesthesia and blood samples collected after 3, 4, 5, 7, 10 and 15 min. Supplements were made to the anaesthetic, where appropriate, and surgery started.

Samples were analysed for blood glucose, serum insulin and cortisol, and plasma catecholamines concentrations, as described previously.[3] For each patient, the insulin response to each ivgtt was calculated as the area under the curve (AUC) from 0 min to the 15 min sample by the trapezium method. The acute insulin response (AIR) was calculated as the absolute increase in insulin concentration from the

Within-group comparison	P<0.05		P<0.05		P<0.02	

baseline sample immediately preceding each ivgtt to the value of the 3-min sample.[4]

Differences in blood glucose values within each group with respect to the baseline sample of each ivgtt were analysed by two-way analysis of variance with Dunnet's test. Differences between the three groups were estimated by one-way analysis of variance. For insulin data, statistical analysis of differences in the calculated AIR and AUC between the three groups, awake and asleep, was by the Kruskal–Wallis test. Within each group, differences between the two ivgtts were analysed by Wilcoxon matched pairs signed rank sum test. P<0.05 was taken to be statistically significant.

We studied 27 patients. At operation, six patients were found to have ovaries with a polycystic appearance and were excluded from analysis. The results from seven patients were evaluated in each group. Median age was 31 (range 26–36), 32 (29–38) and 29 (24–39) yr for the 0, 1 and 2 MAC groups, respectively. Mean weight was 62.2 (SD 3.2), 59.4 (5.9) and 56.7 (7.4) kg, respectively, for the 0, 1 and 2 MAC groups. No patients reported any event which suggested awareness during the study.

In the awake ivgtt, blood glucose increased significantly in all three groups at 3 min by at least 2.6 mmol litre^{-1} (P<0.05). There was no significant difference in glucose values between the three groups of patients. A similar glycaemic response was seen in the ivgtt during anaesthesia, but the increase was significantly greater in the 2 MAC group at 3 min (F= 7.34, P=0.008). At 15 min, blood glucose concentration was greater in the 1 and 2 MAC groups than in the 0 MAC group (F=6.57, P=0.012).

Both AIR and AUC decreased significantly in all three groups during anaesthesia. However, there was no difference between the groups, either awake or anaesthetized, in AIR or AUC (table 1).

There were no significant differences in circulating norepinephrine, epinephrine or cortisol concentrations between the three groups.

Mean arterial pressure (MAP) did not change significantly in any group during the awake ivgtt. It decreased in all groups after induction of anaesthesia, although this was significant only in the 1 and 2 MAC groups (P < 0.05). Changes in heart rate during the study mirrored those of MAP.

Comment

We have found that after induction of anaesthesia, the insulin response to a 5-g ivgtt decreased significantly compared with the same test performed awake. The only relevant previous clinical study of isoflurane used a large dose of glucose (0.33 mg kg^{-1} i.v.) that resulted in circulating glucose values of up to 20 mmol litre^{-1}.[5] More importantly, the investigators did not examine the effects of anaesthesia without volatile supplementation.

The influence on insulin secretion of the other drugs used in this study (morphine, hyoscine, fentanyl, thiopental and nitrous oxide) cannot be excluded. However, these agents were common to all three groups and indicate that short-term exposure to isoflurane in a clinical setting does not further decrease insulin release. A group size of nine was chosen for the clinical studies as this sample size was adequate to decrease insulin secretion two-fold *in vitro*. However, six patients were excluded, and therefore the power of the study was reduced to 45% with a standardized difference of 1.0.

Cardiovascular depression after induction of anaesthesia may lead to a decrease in splanchnic blood flow with a consequent decrease in insulin reaching the peripheral circulation. Isoflurane anaesthesia results in vasodilatation of the splanchnic bed in humans and an increase in blood flow. In dogs, mechanical reduction of pancreatic blood flow was not associated with a proportionate decrease in insulin release.[6] Thus isoflurane is unlikely to have a major inhibitory effect on insulin release mediated by alterations in splanchnic blood flow.

Acknowledgement

Financial support for assays performed in this study was received from the Association of Anaesthetists of Great Britain and Ireland. Full data are available from the authors.

Relationship between end-tidal and arterial carbon dioxide partial pressure using a cuffed oropharyngeal airway and a tracheal tube

Y. NAKATA, T. GOTO, S. UEZONO, F. SASAKI AND S. MORITA

Summary

We have compared the differences between end-tidal $P\text{E}'_{\text{CO}_2}$ and arterial Pa_{CO_2} carbon dioxide partial pressures during general anaesthesia using either a cuffed oropharyngeal airway (COPA) or a tracheal tube (TT) in spontaneously breathing adult patients. After induction of anaesthesia, a COPA was inserted in 20 patients who were allowed to breathe spontaneously. When steady state was reached, $P\text{E}'_{\text{CO}_2}$ and Pa_{CO_2} were recorded. The COPA was removed, the trachea intubated with a TT and spontaneous ventilation allowed to resume. After a stable $P\text{E}'_{\text{CO}_2}$ was re-established, Pa_{CO_2} was measured again and $P\text{E}'_{\text{CO}_2}$ recorded. Mean difference between Pa_{CO_2} and $P\text{E}'_{\text{CO}_2}$ with the COPA was 0.72 (SD 0.45) kPa and with the TT 0.64 (0.40) kPa (ns; paired *t* test). Our results suggest that $P\text{E}'_{\text{CO}_2}$ is a clinically acceptable indicator of Pa_{CO_2} in adults breathing spontaneously via a COPA. (*Br. J. Anaesth.* 1998; **80**: 253–254)

Keywords: anaesthesia, general; equipment, tubes tracheal; equipment, cuffs oropharyngeal; monitoring, carbon dioxide; carbon dioxide, partial pressure; partial pressure, carbon dioxide

The cuffed oropharyngeal airway (COPA) is a new airway device which is being introduced into clinical practice. It is an oral airway with a cuff to seal the pharynx and lift the tongue. It can also be connected directly to the anaesthesia breathing system. It is similar to the laryngeal mask airway (LMA) in that it is designed predominantly for use in spontaneously breathing patients and enables anaesthetists to avoid tracheal intubation. The advantages of the COPA compared with the LMA may be that placement is easier to learn, less traumatic and less stimulating.

When the trachea is intubated with a tracheal tube (TT), end-tidal carbon dioxide partial pressure ($P\text{E}'_{\text{CO}_2}$) is used widely as an indicator of arterial carbon dioxide partial pressure Pa_{CO_2} and hence adequacy of ventilation.[1 2] However, whether or not this holds true for the COPA is unknown. With the COPA the cuff is opposed to the pharynx and the reliability of the seal is in doubt. Therefore, we have compared the differences between $P\text{E}'_{\text{CO}_2}$ and Pa_{CO_2} measured using a COPA or a TT in spontaneously breathing adults during general anaesthesia.

Methods and results

After obtaining approval from the Institutional Human Studies Committee of Teikyo University and informed consent, we studied 20 adult ASA I–II patients undergoing elective surgery. Exclusion criteria were history of cardiac or pulmonary abnormalities, abnormal airway anatomy or any condition which increased the risk of regurgitation of gastric contents or precluded the use of succinylcholine.

The study was designed to duplicate the within-group methods described by Chhibber, Kolano and Roberts.[3] Premedication was decided by the anaesthetist in charge. With subjects lying in the supine position, general anaesthesia was induced with propofol 2–3 mg kg^{-1} i.v. After establishing an adequate level of anaesthesia, the COPA was inserted, positioned and tested according to the manufacturer's instructions. The cuff was inflated with 30–40 ml of air. In general, sizes 9 and 10 were used for females and males, respectively. Head rotation to the side and neck extension were applied if necessary to ensure clinical airway patency.

Subjects were allowed to stabilize while breathing spontaneously a sevoflurane–oxygen mixture. Total fresh gas flow was set at 6 litre min^{-1}. When $P\text{E}'_{\text{CO}_2}$ had been stable for a minimum of 5 min, an arterial blood sample was obtained for measurement of Pa_{CO_2}, and $P\text{E}'_{\text{CO}_2}$ and tidal volume were recorded. The COPA was then removed and the trachea intubated with a TT after administration of succinylcholine 1–2 mg kg^{-1} i.v. Correct positioning of the TT was confirmed by capnography and auscultation of the chest to exclude endobronchial intubation. The TT used for females was 7.5 mm internal diameter (id) and for males 8.0 mm id. Subjects were allowed to recover from neuromuscular block and breathe spontaneously. Anaesthesia was maintained with sevoflurane in oxygen. After a minimum of 5 min of stable $P\text{E}'_{\text{CO}_2}$, a second blood sample was obtained for measurement of Pa_{CO_2}, and $P\text{E}'_{\text{CO}_2}$ and tidal volume were again recorded. During this period, no invasive procedures were performed and stable haemodynamic variables were maintained.

The respiratory gas was sampled at the Y connector and $P\text{E}'_{\text{CO}_2}$ was monitored with an infrared gas monitor (Ultima SV, Datex, Helsinki, Finland) which had been calibrated before each study. Its stated accuracy is ±0.15 kPa. The anaesthesia breathing system used was the adult non-rebreathing system with unidirectional valves. Tidal

Table 1 Performance characteristics of the cuffed oropharyngeal airway (COPA) and tracheal tube (TT) (mean (SD)). $^*P<0.05$ compared with Pa_{CO_2}

	COPA	TT
Tidal volume (ml)	244 (89)	225 (66)
Ventilatory frequency (bpm)	23 (6)	24 (5)
$P\text{E}'_{CO_2}$ (kPa)	5.43 (0.55)*	5.96 (0.75)*
Pa_{CO_2} (kPa)	6.15 (0.64)	6.59 (0.84)
$Pa_{CO_2} - P\text{E}'_{CO_2}$ (kPa)	0.72 (0.45)	0.64 (0.40)

volume was measured with a spirometer (Respirometer RM121, Ohmeda, Mississauga, Ontario) placed at the end of the expiratory limb of the anaesthesia system. Arterial blood samples were analysed immediately with a Stat Profile 9 (Nova Biomedical, Waltham, MA). The analyser underwent two-point calibration before each study. Its accuracy is within 0.02 kPa and coefficient of variance is 3% for carbon dioxide.

Tidal volumes and ventilatory frequencies were analysed using a paired *t* test. Pa_{CO_2} and $P\text{E}'_{CO_2}$ data were compared using two-way analysis of variance with repeated measures.[4] A paired *t* test was performed to establish differences between arterial and end-tidal partial pressures with the COPA and TT. All values are mean (SD). $P<0.05$ was considered statistically significant.

We studied 20 patients (five males, 15 females), weighing 44–85 kg (mean 59.3 kg), aged 21–68 yr (mean 45.2 yr). Three patients were active smokers.

The results are summarized in table 1. There was no significant difference in tidal volume, ventilatory frequency, Pa_{CO_2} or $P\text{E}'_{CO_2}$ before and after intubation. As would be expected, Pa_{CO_2} was greater than $P\text{E}'_{CO_2}$ in all cases. The mean difference between Pa_{CO_2} and $P\text{E}'_{CO_2}$ with the COPA was 0.72 (0.45) kPa and with the TT 0.64 (0.40) kPa (ns; paired *t* test).

Comment

Differences between Pa_{CO_2} and $P\text{E}'_{CO_2}$ were 0.72 (0.45) kPa for the COPA and 0.64 (0.40) kPa for the TT, which are comparable with values obtained in previous studies.[1 2] As with the TT and LMA, the use of the COPA also allows $P\text{E}'_{CO_2}$ to function as a predictor of Pa_{CO_2}.

The use of within-group design excluded multiple confounding factors. Although the sample size in our study appeared to be small, power analysis demonstrated that our sample size had 98% power to detect a difference of 0.40 kPa or greater in $Pa_{CO_2} - P\text{E}'_{CO_2}$ between COPA and TT.[5] Therefore, the similarity in the differences between Pa_{CO_2} and $P\text{E}'_{CO_2}$ for the COPA and TT is unlikely to have resulted from a type II error.

We did not randomize the order of observations, but systematically made the COPA measurements first in order to avoid unnecessary tracheal intubation in surgical patients. This lack of randomization may lead to alteration of ventilation by administration of succinylcholine, stimulus of intubation and a longer anaesthetic when breathing through a TT. However, all respiratory variables (tidal volume, ventilatory frequency, Pa_{CO_2} and $P\text{E}'_{CO_2}$ were similar before and after intubation using repeated measures analysis of variance (table 1). The lack of randomization is not considered to have altered respiratory state.

The COPA is designed to be used in spontaneously breathing patients and the use of controlled ventilation via the COPA has not been reported. In common with the LMA, controlled ventilation via the COPA may place patients at increased risk of aspiration of gastric contents, as gases may be insufflated into the stomach. To avoid this risk of aspiration, we allowed subjects to breathe spontaneously.

In summary, in anaesthetized adults breathing spontaneously via a COPA, $P\text{E}'_{CO_2}$ was as useful in evaluating the adequacy of ventilation as when a TT was used.

The blood–gas partition coefficient of xenon may be lower than generally accepted

T. Goto, K. Suwa, S. Uezono, F. Ichinose, M. Uchiyama and S. Morita

Summary

The blood–gas partition coefficients of xenon, reported more than 25 yr ago in the literature, vary considerably from 0.13 to 0.20. Consequently, we have determined this variable by directly injecting xenon-saturated blood into a gas chromatograph–mass spectrometer. This technique yielded a blood–gas partition coefficient for xenon of 0.115 (95% confidence interval 0.107–0.123). The solubility in water measured identically was 0.096, consistent with the reported value of 0.085. These data and a detailed review of the literature strongly suggest that the blood–gas partition coefficient of xenon may be lower than the generally accepted value of 0.14. (*Br. J. Anaesth.* 1998; **80**: 255–256)

Keywords: anaesthetics gases, xenon; solubility, partition coefficients

Xenon, an inert gas with anaesthetic properties (MAC = 71%), has recently attracted renewed interest because it possesses many of the characteristics of an ideal anaesthetic. Notably, it is extremely insoluble in human tissues, enabling faster induction of, and emergence from, anaesthesia than other inhalation anaesthetics.[1]

The blood–gas partition coefficient of xenon is generally accepted as 0.14.[2] However, the published values vary considerably from 0.13 to 0.20[3–8] and no study specifically documented a value of 0.14. Moreover, all of these measurements were performed more than 25 yr ago. Consequently, we have measured this variable by directly injecting xenon-saturated blood into a gas chromatograph–mass spectrometer. When analysing highly impure substances such as blood, addition of a mass spectrometer to a gas chromatograph results in more accurate identification and complete isolation of xenon because, while a gas chromatograph separates substances solely by the time required for each substance to pass through the column (i.e. retention time), a mass spectrometer further analyses these separated substances by determining their mass–charge ratios after ionization.

Methods and results

Blood (5 ml) was obtained from 10 healthy subjects (five males, five females, aged 21–54 yr). A sample of 2 ml was sent to the clinical laboratory for measurement of packed cell volume and plasma concentrations of albumin, cholesterol and triglycerides. The remaining 3 ml were immediately anticoagulated by adding citrate–phosphate–dextrose (CPD) 0.3 ml (containing per 100 ml: sodium citrate 2.63 g, citrate 0.327 g, glucose 2.32 g and $NaH_2PO_4 \cdot 2H_2O$ 0.251 g). To saturate blood with xenon, the specimen was placed in a 5-ml vial with an air-tight rubber top and stirred for 4 h at 37°C with 99.995% pure xenon (Nippon-Sanso, Tokyo, Japan) continuously flowing over it at a rate of 10 ml min^{-1}. Equilibration periods of 2, 3 and 4 h yielded similar partition coefficients.

Using an air-tight microsyringe, a 2-µl aliquot of each specimen was injected directly into a gas chromatograph (HP5890A, Hewlett Packard, USA) connected to a double-focusing mass spectrometer (AX-505W, JEOL, Tokyo, Japan). The chromatograph column was a 3 mm × 1 m stainless steel tube packed with molecular sieve 5A on 60/80 mesh, which was maintained at 100 °C. Helium was used as the carrier gas at a flow rate of 25 ml min^{-1}. As ^{129}Xe is the most abundant form of naturally occurring stable isotopes of xenon, we measured the area under the curve at the mass–charge ratio of 129 for 10 min after each injection. The mean and coefficient of variation (= SD/mean × 100%) of three measurements were determined for each sample. This mean was compared with the average area under the curve obtained from six injections (three before and three after injection of each specimen) of helium 2 ml containing xenon 10 ppm (Nippon-Sanso, Tokyo, Japan) to yield the solubility expressed as the volume of dry xenon gas dissolved in 1 ml of solvent at 37°C.

The mean solubility of xenon in anticoagulated blood was 0.112 (95% confidence interval 0.104–0.119). The median coefficient of variation was 8.5% (range 1.5–18.9%), implying that the measurements were precise. Solubilities in CPD solution and water were 0.073 and 0.096, respectively. The blood–gas partition coefficient for xenon, after correction for dilution of blood by the CPD solution, was estimated to be 0.115 (95% confidence interval 0.107–0.123) This correction was based on the assumption that (solubility in blood) × 3.0 = (solubility in the anticoagulated sample) × 3.3 − (solubility in the CPD

solution) × 0.3, because 0.3 ml of the CPD solution were added to 3.0 ml of blood.

Mean packed cell volume and concentrations of albumin, cholesterol and triglyceride were 40.4 (SD 5.3)%, 45 (6) g $litre^{-1}$, 4.76 (0.80) mmol $litre^{-1}$ and 1.57 (0.59) mmol $litre^{-1}$, respectively.

Comment

Table 1 summarizes the published blood–gas partition coefficients for xenon. The oldest value of 0.20[8] is questionable because the same group of investigators later published a value of 0.149.[4] Yeh and Peterson[3] extracted dissolved xenon from saturated blood by repeated evacuation and obtained a value of 0.18. In contrast, lower and strikingly consistent values of approximately 0.13 were obtained by introducing radioactive xenon (^{133}Xe) into the gas space contacting the blood sample and simultaneously measuring the radioactivities in the gas and equilibrated blood.[5–7]

Our value of 0.115 determined by gas chromatography–mass spectrometry is estimated to contain an error of approximately ±0.01 because the coefficients of variation were less than 10% for most specimens and because solubility in water was determined as 0.096, approximately 10% higher than the value in the literature (0.085).[2] Thus our result appears to be consistent with those obtained using ^{133}Xe[5–7] but is significantly lower than other values.[3–4 8]

The reason for this discrepancy is unclear, but several possibilities warrant consideration. For example, the higher plasma lipid concentration of Yeh and Peterson[3] (total lipid 720 mg dl^{-1} in their study *vs* our concentrations of cholesterol of 184 mg dl^{-1} and triglyceride 137 mg dl^{-1}) might in part account for their larger value.[9] In contrast, although the solubility of xenon in blood increases linearly with packed cell volume,[5–7] our samples and those of other investigators had similar packed cell volume and haemoglobin concentrations (table 1). Finally, the difference in anticoagulants used (CPD solution compared with the more commonly used heparin) cannot be disregarded but is unlikely to be fully responsible because a larger amount of sodium citrate than we used has only a negligible effect on the solubility of volatile anaesthetics in blood.[10]

In summary, our measurement and a detailed review of the published literature suggest that the blood–gas partition coefficient of xenon may be lower than 0.14, the value currently most frequently cited.

Sevoflurane has less effect than halothane on pulmonary afferent activity in the rabbit†

C. Moores, A. S. Davies and M. Dallak

Summary

We have compared the effects of sevoflurane and halothane on the discharge frequencies of 19 slowly adapting and four rapidly adapting lung receptors in the rabbit by recording from single vagal fibres. Both agents reduced the discharge frequency of slowly adapting receptors during expiration ($P<0.0005$), halothane having a greater effect than sevoflurane ($P<0.0005$). Neither agent had any effect on discharge frequency at the end of inspiration when discharge frequency is at a maximum. Neither agent affected the discharge frequency of rapidly adapting receptors. (*Br. J. Anaesth.* 1998; **80**: 257–259)

Keywords: anaesthetics volatile, sevoflurane; anaesthetics volatile, halothane; lung, receptors; rabbit

Lung receptors include slowly adapting (stretch) receptors (SAR), rapidly adapting (irritant) receptors (RAR) and J receptors. They form the afferent limbs of airway reflexes, including the Hering–Breuer reflex, reflex bronchoconstriction and the cough reflex.

The activity of these lung receptors has been shown to be influenced by volatile anaesthetic agents such as chloroform, ether,[1] halothane, isoflurane and enflurane.[2] Nishino, Anderson and Sant'Ambrogio found that the modern agents increased the firing threshold of SAR while at the same time increasing their discharge frequency above this threshold. They also found that increasing concentrations of volatile agents decreased the activity of RAR. They could not demonstrate a quantitative difference between the agents on either receptor type.[2]

To date, sevoflurane has not been studied. It differs from other volatile agents in that it appears to be much less irritating to the airway, being associated with a lower incidence of airway-protective reflexes.[3] It seems likely, therefore, that sevoflurane may also have a different effect on intrapulmonary receptors. In this study, we compared the effect of halothane and sevoflurane on the activity of intrapulmonary receptors measured from single vagal fibres in rabbits undergoing ventilation.

Methods and results

After obtaining approval from the Home Office, we studied four New Zealand White rabbits. Each was anaesthetized with 25% urethane 7 ml kg^{-1}. The femoral vein was cannulated to allow i.v. injections, and the femoral artery was cannulated for measurement of arterial pressure and heart rate. The trachea was cannulated, the rabbit paralysed with vecuronium 0.2 mg kg^{-1} and its lungs ventilated with air using a tidal volume of 6 ml kg^{-1} and a ventilatory frequency of 80 bpm to maintain end-tidal carbon dioxide partial pressure close to the level measured before ventilation. Airway flow was measured using a pneumotachograph, the flow signal being integrated electronically to give volume (CS5, Griffin). End-tidal concentrations of anaesthetic gas and carbon dioxide were measured continually (Capnomac Ultima, Datex).

Both vagi were divided in the neck to prevent reflex bronchoconstriction which may influence SAR activity. The distal end of the left vagus was desheathed and divided into thin filaments. Recordings were made from these filaments using bipolar platinum electrodes and nerve discharges were displayed on an oscilloscope and fed to a loudspeaker. Further subdivision of each filament continued, until a filament was found containing a single active nerve fibre from a pulmonary afferent. The single fibre was identified as originating from either a pulmonary stretch receptor or rapidly adapting receptor on the basis of its pattern of firing during the respiratory cycle and its response to short pulses of either positive or negative pressure.

The lungs were ventilated with oxygen for 2 min and then either sevoflurane or halothane was introduced at a concentration of 2% for 1 min followed by 5% for 1 min. The rabbit's lungs were then ventilated with oxygen for 2 min. Thereafter, 2% and 5% of the second agent was introduced as for the first. The vagal filament was then discarded, another filament was dissected from the vagus and the procedure repeated. The order in which the volatile agents were used was reversed in consecutive procedures.

Nerve impulses were converted into 5-V electronic pulses using a windows discriminator (Neurolog, Digitimer Ltd). Airway flow and pressure, tidal

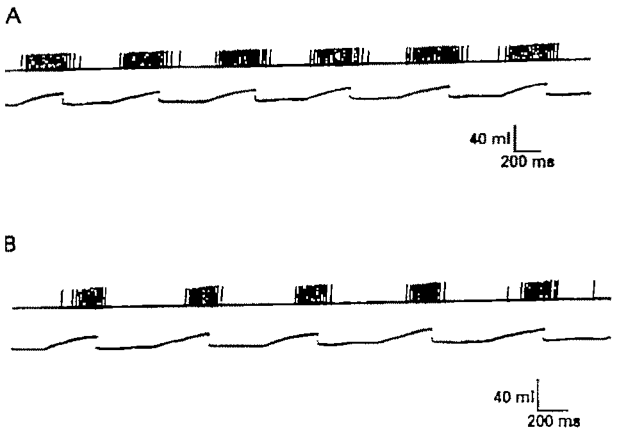

Figure 1 A: Slowly adapting receptor activity and inspired volume during control conditions. The upper trace shows 5-V processed nerve impulses and the lower trace inspired volume (integrated flow signal). Receptor activity increased with increasing lung volume and decreased to a minimum during expiration. B: Impulses from the same receptor exposed to 5% halothane. The threshold at which firing commenced was higher, but the maximum rate of firing was unchanged.

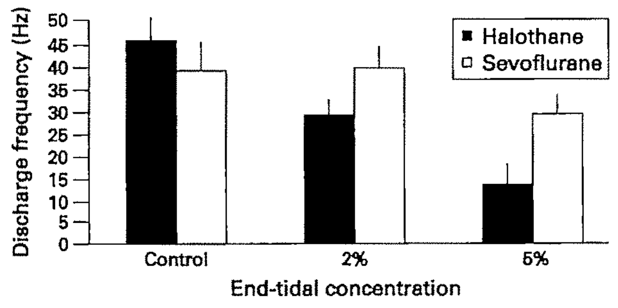

Figure 2 Mean (SEM) discharge frequency of slowly adapting receptors during expiration. Concentration effects and difference between agents were significant ($P<0.0005$).

volume, arterial pressure and nerve impulses were recorded onto eight-track magnetic tape (XR30, TEAC). Statistical analysis was performed using repeated measures ANOVA (SPSS for Windows.)

Recordings were made from 23 single fibres: 19 from SAR and four from RAR.

SLOWLY ADAPTING RECEPTORS

Figure 1A shows the characteristic discharge pattern of an SAR during the respiratory cycle. With increasing lung volume the discharge frequency of the receptor increases. Figure 1B illustrates the discharge pattern of the same receptor during administration of 5% halothane. This receptor ceases to discharge for a period during expiration; however, some receptors discharged throughout the respiratory cycle, and therefore separate analysis of discharge frequency during inspiration and expiration was necessary, rather than analysis of the duration of discharge of the receptors.

Expiration

During expiration, the effect of both halothane and sevoflurane is to reduce the receptor discharge frequency. Figure 2 demonstrates the effect of increasing concentration on receptor discharge frequency during expiration, when discharge frequency is at a minimum. The decrease in discharge frequency with increasing concentration was significant ($P<0.0005$). Halothane had a significantly greater effect than sevoflurane in reducing discharge frequency during expiration ($P<0.0005$).

Inspiration

During inspiration, we were unable to demonstrate any effect of either agent on receptor discharge frequency. Mean discharge frequency during the final 100 ms of inspiration for halothane was 107.7 (SEM 6.5) Hz (control) and 106.7 (7.2) Hz (5% end-tidal concentration), and for sevoflurane 103.5 (7.0) Hz (control) and 114.5 (7.1) Hz (5% end-tidal concentration).

RAPIDLY ADAPTING RECEPTORS

During the course of this investigation, we recorded from only four RAR as these receptors form a small proportion of the lung receptors in the rabbit. Measurements of nerve discharge frequency were averaged over a 5-s period. At the concentrations used, we found no significant effect of either agent on the discharge frequency of the RAR. Mean discharge frequency for halothane was 6.1 (SEM 1.9) Hz (control) and 6.7 (1.7) Hz (5% end-tidal concentration), and for sevoflurane 5.6 (1.9) Hz (control) and 7.7 (1.2) Hz (5% end-tidal concentration)

In the case of two receptors, we recorded airway pressure. There was no significant change in maximum airway pressure during ventilation with either volatile agent, suggesting that they did not cause a significant degree of bronchodilatation which may have altered SAR activity. Mean maximum airway pressure during ventilation for halothane was 1.39 (SEM 0.1) cm H_2O (control) and 1.49 (0.1) cm H_2O (5% end-tidal concentration), and for sevoflurane 1.39 (0.1) cm H_2O (control) and 1.44 (0.1) cm H_2O (5% end-tidal concentration).

Comment

We have shown that the predominant effect during expiration of halothane and sevoflurane is to decrease the discharge frequency of SAR. This represents an increase in the discharge threshold of the receptors, and confirms the findings of Nishino, Anderson and Sant'Ambrogio using halothane, isoflurane and enflurane.[2] Nishino, Anderson and Sant'Ambrogio did not demonstrate a significant quantitative difference between the effect of these agents on SAR; we found that halothane had a significantly greater effect than sevoflurane on the discharge frequency of SAR during expiration. Sevoflurane has less effect than other agents on upper airway receptors, as manifest by its low level of airway irritability, and it is interesting that it also had less of an effect on lung SAR.

We did not demonstrate an effect of either volatile agent on the discharge frequency of SAR at the end of inspiration when their firing rate is at a maximum. Other workers have found in decerebrate cats that the modern agents sensitize these receptors above their firing threshold.[2] It is possible that had we used larger tidal volumes, applying a greater stimulus to these receptors, their discharge frequency at end-expiration may have been influenced by the volatile agents.

SAR form part of the Hering–Breuer inflation reflex which in animals is important for the control of breathing pattern.[4] Halothane and sevoflurane produce tachypnoea in animals and humans.[5 6] The increase in ventilatory frequency that is seen in animals during anaesthesia with halothane is smaller after vagotomy,[7] suggesting that changes in lung afferent activity are partly responsible presumably via the Hering–Breuer reflex. In both animals and humans, tachypnoea during anaesthesia with sevoflurane is less than that with halothane and vagotomy does not alter the increase in ventilatory frequency that sevoflurane causes in decerebrate cats.[7] It is possible that the differences between halothane and sevoflurane in animals may be caused by differences in the sensitivity of SAR to the two agents, although a central cause cannot be excluded. Although in anaesthetized humans there is little evidence that the Hering–Breuer reflex is important in modulating eupnoeic breathing,[8 9] the effect of volatile agents on lung receptors could possibly result in the modulation of other airway reflexes, such as the cough reflex, reflex bronchodilatation and bronchoconstriction.

CASE REPORT

Propofol and electroconvulsive therapy in a patient at risk from acute intermittent porphyria

I. H. SHAW AND I. G. MCKEITH

Summary

A severely depressed 57-yr-old woman at risk from acute intermittent porphyria presented for a course of electroconvulsive therapy. With propofol as the induction agent the course of electroconvulsive therapy was both uneventful and successful. (*Br. J. Anaesth.* 1998; **80**: 260–262)

Keywords: anaesthetics i.v., propofol; brain, electroconvulsive therapy; complications, porphyria

Acute intermittent porphyria (AIP) may be induced in susceptible patients by several commonly used anaesthetic drugs.[1] Isolated case reports suggest that propofol may be a safe alternative in such patients. Propofol has also been reported to reduce the duration of seizure activity during electroconvulsive therapy (ECT) and as a consequence doubts have been expressed about the efficacy of ECT after anaesthesia with propofol.[2 3]

Case report

A 57-yr-old woman suffering from Parkinson's disease presented with a major depressive disorder as part of an organic affective syndrome. She had paranoid and nihilistic delusions and was refusing food and fluids. As these symptoms had failed to respond to drug therapy ECT was felt to be the only alternative. The patient was a member of a large family with a history of autosomally dominant AIP.

Her red blood cell porphobilinogen deaminase (PBG-D) activity was abnormally low (12.7 nmol porphyrin formed/ml erythrocytes/h; normal range 30–54) confirming that she too had AIP. Urinary porphyrins were normal. The patient gave no history of having suffered from a symptomatic episode of AIP.

At the preanaesthetic assessment the woman, who weighed 45 kg, was noted to be tremulous, bradykinetic and rigid, consistent with Parkinson's disease. She was normotensive and no abnormality was found on cardiorespiratory examination, but the ECG indicated changes consistent with an old anteroseptal myocardial infarction. The patient denied having suffered from cardiorespiratory symptoms. Apart from borderline hypokalaemia, all routine laboratory investigations were normal. Her current medication was pergolide, cobeneldopa, benzhexol, thyroxine and lofepramine.

A total of seven ECT treatments were administered in the ECT suite over a period of 23 days. ECG, arterial pressure and oxygen saturation were monitored routinely. After 1 min of preoxygenation with 100% oxygen, anaesthesia was induced with propofol and neuromuscular block facilitated by succinylcholine. Bilateral ECT was administered after a brief period of hyperventilation with 100% oxygen and seizure duration was timed from application of the current (table 1).

In our patient mean seizure time was 31 (range 16–55) s and aggregate seizure duration was 218 s. The patient was monitored during recovery while breathing 35% oxygen. Administration and conduct of all seven treatments was uneventful. In total, the patient had received propofol 450 mg (mean induction dose 64 (range 60–80) mg) over a 23-day period.

No urinary porphyrins or blood porphobilinogen were detected when measured on day 14 after the fourth treatment. During the course of the ECT the patient remained an inpatient on a neurological ward where the staff were particularly vigilant for signs and symptoms of AIP. At no time did the patient's neurological condition give cause for concern. At the end of treatment her mood had returned to normal with full remission of her psychotic symptoms.

Discussion

The porphyrias are a group of uncommon inherited metabolic disorders in which there is a disturbance of haem synthesis. In AIP a deficiency of porphobilinogen deaminase (PBG-D) results in the accumulation of the intermediate metabolites porphobilinogen (PBG) and animolaevulinic acid (ALA). AIP can be induced by many drugs familiar to the anaesthetist, in particular the barbiturate induction agents.[1 4] Clinically, symptoms may be severe and of rapid onset. Abdominal pain, paralysis, mania, coma and death can ensue.

In recent years conflicting reports have appeared in the literature on the porphyrogenicity of propofol. Several reports have shown that a single induction dose had no adverse clinical effect.[5–7] Mitterschiffthaler and colleagues[8] reported the safe use of

propofol on two occasions in a susceptible patient within a 2-week period, and Harrison and McAuley[9] successfully sedated a patient with symptomatic life-threatening AIP for 32 days in intensive care. An *in vivo* rat model failed to find any evidence of the porphyrogenicity of propofol.[10] Increase in urinary porphyrins after propofol anaesthesia has been reported in susceptible patients.[11 12] On one occasion this was only after a third propofol anaesthetic. In both reports patients remained asymptomatic and anaesthesia was otherwise uneventful. Kasraie and Cousins[13] reported a patient who was readmitted with an acute symptomatic attack of coproporphyria 4 days after propofol anaesthesia. However, the patient had also been exposed to several other potentially porphyrogenic drugs, the significance of which is uncertain.

Our patient received seven propofol anaesthetics over a 23-day period without biochemical or clinical evidence of induced AIP. Of interest is Kauppinen and Mustajoki's[14] findings that patients with AIP who have never experienced any symptoms, particularly if they have low concentrations of urinary porphyrin precursors, appear to tolerate precipitating drugs well. The authors proposed a more permissive attitude to the administration of potentially porphyrogenic drugs in previously totally asymptomatic patients. In those patients known to have had a previous attack, the exclusion of such drugs was regarded as mandatory. Our patient had been asymptomatic all her life.

One concern expressed in previous isolated case reports is that not every administration of a porphyrogenic drug induces porphyria and consequently many reports have concluded with a warning about the use of propofol in patients at risk from acute porphyria[11-13] and that perioperative biochemical monitoring should always be carried out. For a detailed discussion of anaesthesia for the porphyric patient the reader should consult the review by Harrison, Meissner and Hift.[1]

For a course of ECT to be effective a minimum aggregate seizure duration is thought to be necessary.[15] Preoxygenation and ventilation with 100% oxygen during ECT has been shown to prolong seizure duration,[16] as has hypocapnia induced by passive hyperventilation.[17] Several reports have been published which show that propofol anaesthesia reduces seizure duration[2 3 18 19] and as a consequence the manufacturers have recommended that propofol is unsuitable for use in ECT.

Avramov, Husain and White[20] demonstrated a dose-dependent decrease in seizure duration with both methohexital and propofol. The authors concluded that induction doses of propofol in excess of 1.5 mg kg^{-1} significantly reduced seizure duration. Smaller doses of propofol in the range 0.75–1.0 mg kg^{-1} were similar to commonly used doses of methohexital. Our patient received propofol in the dose range 1.3–1.7 mg kg^{-1}. In another comparative study,[19] seizure duration was also reduced after propofol. The efficacy of ECT was found to be unaffected by the choice of propofol as the anaesthetic induction agent compared with methohexital. This finding was also observed by Kirkby and colleagues.[21]

A seizure duration of more than 25 s is often quoted as being necessary for ECT.[22] However, observed seizure duration is usually less than that demonstrated by simultaneous EEG recording. On this basis, with the exception of the third treatment, most of our patient's seizure times could be regarded as adequate. The aggregate seizure duration over seven treatments was sufficient to bring about a beneficial clinical response. The crucial test as regards the efficacy of ECT is whether the patient responds to the treatment as expected.[22]

Our patient with AIP had an uneventful and successful course of ECT using propofol as the anaesthetic agent. The barbiturate anaesthetic methohexital is still regarded by many as the anaesthetic agent of choice for ECT. The known porphyrogenicity precluded its use in our patient. Ketamine, an anaesthetic known to be safe in porphyria, was felt to be particularly unsuitable for ECT in our patient because of its known hallucinogenic effects.

Unfortunately, approximately 9 months later the patient had a relapse of her depressive illness necessitating a further course of ECT. Again propofol was used as the induction agent with success and without ill effect.

Commentary

Mapleson WW. The elimination of rebreathing in various semi-closed anaesthetic systems. *British Journal of Anaesthesia* 1954; **26**: 323–332.

The first anaesthesia breathing systems were developed for delivery of nitrous oxide–oxygen mixtures for dental anaesthesia. While some of the earlier machines used wide bore tubing to connect the machine to the patient, most used a 1–2-m length of narrow bore tubing to transfer the gas mixture to the reservoir bag and expiratory valve which were situated close to the face mask. Both the Gwathmey–Woolsey apparatus of 1912 and the close copy introduced by Boyle at the beginning of World War 1 used this arrangement. However, when Magill was anaesthetizing for reconstructive surgery after the war, he found that the presence of the bag close to the patient's face interfered with the work of the plastic surgeon, and therefore he moved the bag to the machine end of the connection tubing. By this time Magill was moving from insufflation anaesthesia to the use of a wide bore tracheal tube, and this made him realize that the connecting tubing would have to be of wide bore to reduce the resistance to breathing. The supply problem was solved initially by using corrugated tubing from First World War gas masks to connect the bag to the expiratory valve. Although the to and fro carbon dioxide absorption system was introduced by Waters in 1924 and the circle carbon dioxide absorption system followed in 1930, these systems were never used widely in the UK, their use tending to be restricted to situations where cyclopropane was required. For most other applications the Magill system retained its popularity in the UK for more than 50 yr.

When Mapleson was appointed to the post of physicist in the Cardiff department he found that anaesthetists were using several different semi-closed systems and to reduce confusion, he classified these alphabetically. "A" was the standard Magill breathing system with a tube of approximately 22 mm internal diameter and an internal volume of approximately 500 ml. "B" was a system made by Medical and Industrial Equipment Ltd which appeared to be similar to the "A" system, but in which fresh gas flow was diverted from the machine common outlet through a narrow bore tube to rejoin the breathing system by the expiratory valve. It was claimed that this arrangement enabled inspired gas concentrations to be changed rapidly, and that it decreased rebreathing, but as Mapleson's diagram showed, the metal diaphragm in the bag mount which diverted the gas flow into the narrow bore tube caused the corrugated tube and reservoir bag to become one large rebreathing chamber. The "C" system was that used on the original Boyle's machine, but in 1954 it would have been produced by removing the carbon dioxide absorption canister from the Water's to and fro system. Such a system was used frequently for transport or resuscitation of patients in the days before self-inflating bags and reliable non-rebreathing valves were available. System "E" was the Ayre's T-piece, introduced for paediatric anaesthesia in 1937, and system "D" was the Jackson Rees modification used with controlled ventilation.

In the 1950s most anaesthetists using the Magill system set flowmeters to deliver 2 litre of oxygen and 5 litre of nitrous oxide, although there was little evidence to support this choice. Molyneux and Pask had used a primitive pneumotachograph to record flows on the patient side of the reservoir bag and had concluded that much higher flows were needed to prevent rebreathing.[1] However, Mapleson concluded from his theoretical analysis that rebreathing would be prevented if fresh gas flow was greater than alveolar ventilation. This definition of rebreathing recognized that re-inhalation of gas which had come from the apparatus and patient's deadspace (and which therefore did not contain carbon dioxide) had no effect on gas exchange. In order to render the mathematics simple enough for the average anaesthetist to understand, Mapleson made five simplifying assumptions. These were examined in detail, and although none appeared likely to have a gross effect on the prediction, Mapleson cautiously modified his conclusion and stated that rebreathing of carbon dioxide-rich gas would be prevented completely if the fresh gas flow rate exceeded the patient's minute volume with system A, and that a flow rate approximating to twice the patient's minute volume was required with the other systems.

Mapleson's prediction that there would be no rebreathing with the "A" system if fresh gas flow exceeded minute volume was soon confirmed by experiments on lung models and observations in the operating theatre, but it was not until 1967 that Kain and Nunn confirmed in anaesthetized patients that fresh gas flow could be reduced to approximately 70% of minute volume before rebreathing occurred.[2]

In the 1950s the "A" system was used frequently when assisting or controlling ventilation during short operations such as appendicectomy. Under these circumstances a mixture of fresh and expired gas is discharged from the valve during inspiration. This results in a variable degree of rebreathing.[3] Waters and Mapleson went on to provide a theoretical analysis of the performance of systems "A", "B", "C" and "D" during controlled respiration and concluded that system "A" was the least efficient.[4] However, their observations in five patients indicated that end-tidal $P\text{CO}_2$ could be maintained within normal limits with all four systems when fresh gas flow was increased to 8 litre min^{-1}.

Mapleson's clear analysis of the dynamics of these breathing systems shows how important it is for the anaesthetist to have an understanding of simple physics and mathematics. It has also stimulated others to design breathing systems which preferentially dump the carbon dioxide-containing moiety of expired gas, and so decrease fresh gas requirements. But, above all, this article marked the arrival on the anaesthetic scene of one who has made many major contributions to our knowledge of the scientific basis of anaesthesia. It is a pleasure to acknowledge his selfless devotion to our specialty.

THE ELIMINATION OF REBREATHING IN VARIOUS SEMI-CLOSED ANAESTHETIC SYSTEMS

BY

William W. Mapleson
The Department of Anaesthetics
The Welsh National School of Medicine, Cardiff

INTRODUCTION

A VALUABLE theoretical and experimental analysis of the flow of gases in a semi-closed anaesthetic system was published by Molyneux and Pask in 1951. Their theoretical analysis was applied to one particular type of system and involved the assumption of certain idealized characteristics of the expiratory valve and of the breathing pattern. In the present work it is proposed to extend the theoretical analysis to other types of semi-closed systems and to take account of the effects of the actual characteristics of the expiratory valve and reservoir bag and of breathing patterns other than the idealized one.

In all, five systems will be considered (A, B, C, D, E in figure 1) of which A was analyzed by Molyneux and Pask.

SYSTEM A

Expiratory valve close to face mask, separated by corrugated tube from reservoir bag and supply of fresh gases.

In this simple analysis the following assumptions will be made:

(1) Gas enters the system from the anaesthetic machine at a constant volume flowrate F_a.

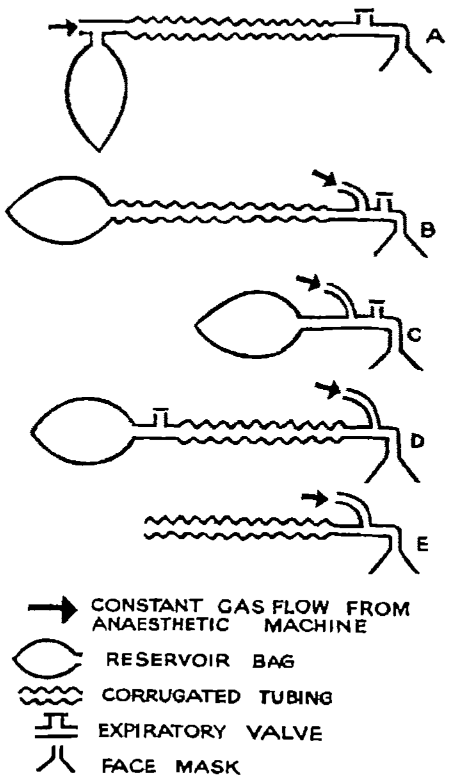

Fig. 1

The five semi-closed anaesthetic systems.

(2) At the start of inspiration the flow-rate into the lungs rises instantaneously to some value greater than F_a. No other assumption need be made as to the nature of the breathing pattern.

(3) The expiratory valve opens when the pressure in the system exceeds some critical value slightly above atmospheric and the valve will pass large flows without further increase in the pressure drop across it.

(4) The system is in a stable state—that is to say the conditions at any particular moment in the cycle of respiration are constant from one respiration to another.

(5) "Plug" flow occurs in the corrugated tubing, face mask and patient's trachea—that is, no longitudinal mixing occurs in these regions.

During expiration gases will enter the system at a known constant rate, F_a, from the anaesthetic machine and an unknown varying rate, say f_r, from the patient. Initially the fresh anaesthetic gases will flow directly into the bag while the expired gases will flow back along the corrugated tubing, forcing gas from the tubing into the bag. When the bag volume rises to some critical value, say V_c, at which the pressure inside it is equal to the opening pressure of the expiratory valve, the valve will open. Then, in virtue of assumption 3, the pressure in the system will not rise further and the volume of the bag will remain constant at V_c. The expired gases will flow directly out through the valve at an unknown varying rate which may still be represented by f_r, while the fresh anaesthetic gases will flow forward along the corrugated tubing still at the known constant rate F_a, forcing out through the expiratory valve gas which had previously entered the corrugated tube from the patient at the beginning of expiration. Apart from the variation of f_r conditions will then remain constant until the start of inspiration.

At the start of inspiration, in virtue of assumption 2, gas will be drawn from the system by the patient faster than it enters from the anaesthetic machine. The additional gas must necessarily be drawn from the reservoir bag whose volume will therefore decrease. Immediately this volume reduction starts there will be a corresponding reduction in the pressure in the system (Mapleson, 1954) below the opening pressure of the expiratory valve which will consequently close immediately inspiration begins. Thereafter conditions will remain steady, the bag slowly emptying, until the rate of inspiration, f_r, falls below the rate of supply of fresh gases, F_a, when the bag will begin to refill. When expiration commences the bag will fill comparatively rapidly in the manner described at the beginning of this analysis.

Now let V_t = patient's tidal volume.

T_1 = time from the start of one inspiration to the end of the same inspiration.

T_2 = time from the end of one inspiration to the start of the next inspiration.

T = duration of one complete respiratory cycle = $T_1 + T_2$.

T' = time from the end of inspiration to the opening of the expiratory valve.

Then the volume drawn from the bag during inspiration will be $V_t - F_a T_1$.

This volume is replaced during expiration in a time, T'. A portion, $F_a T'$, will come direct from the anaesthetic machine, while the remainder, $V_t - F_a T_1 - F_a T'$, will come from the patient. This last volume, $V_t - F_a T_1 - F_a T'$, is thus the volume of expired gas which enters the corrugated tubing and, at the instant at which the valve opens, will reside in the right-hand end of the tube (fig. 1, A), assuming, as one reasonably may in all normal circumstances, that this volume is less than the volume of the corrugated tubing. During the remainder of the time $T_2 - T'$ before the next inspiration, a volume, $F_a T_2 - F_a T'$, of fresh anaesthetic gas will enter the corrugated tubing from the machine at the left (fig. 1, A) and drive out through the expiratory valve at the right an equal volume of the expired gases residing in the right-hand end of the tubing. At the start of the next inspiration, therefore, the volume of expired gas still remaining in the corrugated tubing will be $V_t - F_a T_1 - F_a T' - F_a T_2 + F_a T' = V_t - F_a T$. However, this volume will be composed of gas which was breathed out at the beginning of expiration. Therefore, provided this volume does not exceed V_d, the dead space of the patient plus mask, it will not contain any gas which has been in contact with the alveoli of the lungs—that is to say, it will not contain any "contaminated" gas. Thus a criterion for the elimination of rebreathing may be expressed mathematically by:

$$V_t - F_a T \leqslant V_d$$

or

$$F_a \geqslant (V_t - V_d)/T \text{..........} (1)$$

Now V_t/T is one tidal volume divided by the period of one respiratory cycle and consequently is equal to the minute volume.* Similarly, $(V_t - V_d)/T$ may be referred to as the "effective" minute volume, since it is equal to the average rate of supply of fresh gases to the alveoli of the lungs. Then the criterion for the elimination of rebreathing may be expressed in words by:

> "The volume flowrate of anaesthetic mixture must be not less than the patient's effective minute volume."

It will be realized that this criterion is considerably at variance with that established by Molyneux and Pask. This is due, of course, to the different assumptions made in the present analysis. It is now proposed to examine the effect of various inaccuracies involved in some of these assumptions.

Assumption 5 clearly represents a highly idealized state of affairs; some longitudinal mixing is bound to occur in the system so that when equation (1) is just satisfied some "contaminated" expired gas will, in fact, still reside in the corrugated tubing at the beginning of inspiration and will consequently be rebreathed. In order to *ensure* the elimination of rebreathing, therefore, the criterion:

$$F_a \geqslant V_t/T \text{..............} (2)$$

might be adopted. That is to say that the flow of fresh gas must be not less than the patient's actual minute volume. It imposes the condition that in the absence of mixing none of the gas from the previous expiration shall remain in the system at the start of inspiration. Since mixing will occur some small volume of expired gas will in

---

* Minute volume (F_m) = tidal volume (V_t) × number of respiratory cycles per minute (n). Now, $n = 1/T$ (T in minutes); therefore, $F_m = V_t/T$.

fact remain (an equal volume of fresh gas having escaped through the expiratory valve to maintain the balance) but it will probably consist mainly of gas which has not been in contact with the alveoli of the lungs. Molyneux and Pask took an even stricter condition: namely, that the volume of expired gas which *initially* flows back into the corrugated tube shall not exceed the total deadspace. That is to say

$$V_t - F_a (T_1 + T') \leqslant V_d$$

or

$$F_a \geqslant (V_t - V_d) / (T_1 + T') \text{.....} (3)$$

Even with this condition, however, it is still just possible that mixing would lead to some small amount of rebreathing. In the limit, therefore, it could be assumed that rebreathing will be completely eliminated only if no expired gas is allowed to enter the corrugated tube at any time. That is to say $V_t - F_a (T_1 + T') \leqslant O$ or, since in this condition T' must equal O

$$F_a \geqslant V_t/T \text{..............} (4)$$

(If the periods of inspiration and expiration are equal this is equivalent to saying that the flow of fresh gases must be at least equal to twice the actual minute volume.) If no mixing occurred a graph of percentage rebreathing against the ratio F_a/F_m where F_m is the actual minute volume would appear somewhat as the solid line of figure 2. With mixing, the graph would be modified to something like that shown by the dotted line in the same figure. It would appear that the only way to determine the exact nature of the dotted line would be to perform rapid continuous gas analysis within the semi-closed system. Until this is done and until an acceptable minimum percentage of rebreathing is agreed, it seems that the choice of the condition to establish a criterion for the effective elimination of rebreathing is largely arbitrary. In the author's opinion, quite a small increase in the flow of fresh gases above the minimum required by equation (1) would probably be sufficient to reduce the amount of rebreathing to an acceptably low level.

Instead of making assumption 2, let account be taken of the measurements of Proctor and Hardy (1949), which show that with a patient inspiring against negligible resistance (which will be the case in these semi-closed systems) the inspiratory flowrate increases gradually (though rapidly), and not instantaneously, at the beginning of inspiration. Thus there will be some short period of duration, say T_3, at the beginning of inspiration during which the inspiratory flowrate will be less than the flow of fresh gas from the machine. During this period, therefore,

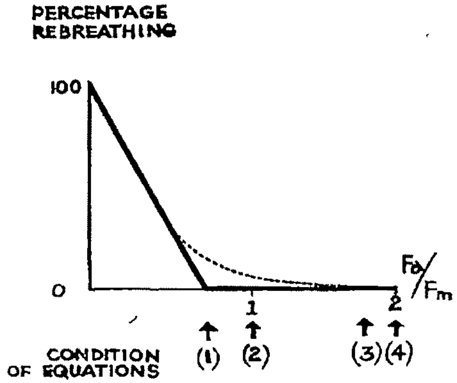

FIG. 2

Graph of percentage rebreathing against the ratio F_a/F_m (flowrate of fresh gases over patient's minute volume) for system A. Solid line: theoretical curve in the absence of longitudinal mixing. Broken line: assumed curve in the presence of mixing some of the gas in the right-hand end of the tube will enter the patient and some will leave through the expiratory valve. This state of affairs will persist until the inspiratory flowrate exceeds F_a when the valve will shut and the bag volume begin to decrease.

During this period a volume of gas, $F_a T_3$, will flow from the anaesthetic machine. If the rate of increase of inspiratory flow is constant during this period, half of this volume, namely $F_a T_3/2$, will enter the patient, and half will leave through the expiratory valve. Now during the remainder of the inspiration the patient will draw the remainder of the tidal volume, $V_t - F_a T_3/2$, and the anaesthetic machine will supply a volume, $F_a(T_1 - T_3)$ of fresh gas. The difference, $V_t - F_a T_1 + F_a T_3/2$, will be drawn from the bag. At a time T' after the end of inspiration, the bag will have regained its critical volume V_c, $F_a T'$ coming from the anaesthetic machine and the remainder, $V_t - F_a(T_1 - T_3/2 + T')$, coming from the patient's expiration (into the right-hand end of the corrugated tube). During the rest of the time up to the start of inspiration $(T_2 - T')$ a volume, $F_a(T_2 - T')$, of fresh gas will enter the left-hand end of the tube, driving out through the expiratory valve all but $V_t - F_a(T_1 - T_3/2 + T') - F_a(T_2 - T') = V_t - F_a(T - T_3/2)$ of the patient's expiration. Then, assuming that no longitudinal mixing occurs, it is this volume which must contain no "contaminated" expired gas if rebreathing is to be eliminated.

That is $V_t - F_a(T - T_3/2) \leqslant V_d$

or $F_a \geqslant (V_t - V_d)/(T - T_3/2)$......(5)

From the graphs given by Proctor and Hardy it is apparent that, when F_a is about equal either to the effective or to the actual minute volume of the patient, T_3 is only about a tenth of T so that equation (5) differs only by a twentieth or a factor 1.05 from equation (1) and it is apparent that assumption 2 introduces no appreciable error.

Now let assumption 3 be modified to take account of the increase in pressure drop across the valve which occurs with an increase of flow through the valve (Mushin and Mapleson, 1954). Let the expiratory valve close at a time, T_4, after the start of inspiration and during this period let the patient inspire a volume, V_p. When the valve closes the bag volume will be V_c and therefore at the end of inspiration it will be say, $V_1 = V_c - \{V_t - V_p - F_a(T_1 - T_4)\}$. Let the bag volume at the beginning of inspiration be V_2. Then the net flow of expired gas into the corrugated tube will be $V_2 - V_1 - F_a T_2 = V - V_c + V_t - V_p - F_a(T - T_4)$. This must be not greater than V_d for the elimination of rebreathing, in the absence of mixing. Therefore

$$F_a \geqslant \frac{V_t - V_d + (V_2 - V_c - V_p)}{T - T_4} \quad .....(6)$$

In order to allot numerical values to the quantities $(V_2 - V_c - V_p)$ and T_4 it is necessary to assume some definite shape for the respiratory flowrate curve and to apply a somewhat lengthy mathematical analysis which it is felt would be somewhat out of place here. However, it can be shown that under all conditions of respiration and valve and bag characteristics likely to be encountered in clinical practice the minimum value required for F_a in order to eliminate rebreathing while being, of course, greater than $(V_t - V_d)/T$ (the effective minute volume) will not be so great as V_t/T (the actual minute volume).

Assumptions 1 and 4 merely restrict the applicability of the analysis to steady conditions.

Thus it seems probable that the errors introduced by assumptions 2, 3 and 5 could be allowed for by adopting equation 2 rather than equation 1. That is to say that it is probably safe to assume that in system A rebreathing of gas which has been in contact with the alveoli of the lungs will be almost completely prevented if the flow of fresh anaesthetic gas is at least equal to the patient's minute volume.

SYSTEM B

Expiratory valve and supply of fresh gases close to face mask, separated by corrugated tube from reservoir bag.

The same assumptions will be made here as for system A. Some time during expiration the bag will fill to the critical volume V_c, and the expiratory valve will open, fresh gas passing directly out at a rate F_a and expired gas at f_r. At the start of inspiration the valve will close and gas will enter the patient at a rate F_a from the machine and a rate $f_r - F_a$ from the corrugated tubing and bag until the full tidal volume V_t has been drawn. Then, at the start of expiration, fresh gas will flow at a rate F_a and expired gas at a rate f_r back along the corrugated tube until the bag volume again reaches V_c and the valve again opens.

Now the volume drawn from the corrugated tube and bag during inspiration $= V_t - F_a T_1$. Of this, $F_a T'$ will be replaced by fresh gas and the remainder, $V_t - F_a T_1 - F_a T'$, by expired gas. This gas will remain in the corrugated tube until inspiration begins since, when the expiratory valve is open, the fresh gases will leave directly through it instead of displacing expired gas from the tube as in system A.

Thus the amount of gas which will be rebreathed is $V_t - F_a T_1 - F_a T'$. Since this rebreathed gas entered the corrugated tubing at the start of expiration, it may be assumed that the rebreathing of contaminated gas will be eliminated if

$$V_t - F_a T_1 - F_a T' \leqslant V_d$$

that is, if $F_a \geqslant (V_t - V_d)/(T_1 + T')$...(7)

Now unless some assumption is made as to the form of the expiratory flowrate curve, T' is indeterminate. However, it must be less than T_2 and therefore $T_1 + T'$ must be less than T. Thus to eliminate rebreathing the flow of gases from the anaesthetic machine must exceed some value which itself is appreciably greater than the patient's effective minute volume. Thus a higher flowrate is needed in this system than in system A.

As in system A, equation (7) holds good only on the assumption (No. 5) that no mixing occurs in the patient's trachea and the face mask. If mixing is assumed to occur there, then the volume of expired gas which is permitted to enter the corrugated tube must be more severely restricted and in the limit *no* expired gas can be permitted to enter it. That is to say, $V_t - F_a T_1 - F_a T' \leqslant O$. Since T' must now equal O,

$$F_a \geqslant V_t/T_1 \quad ....(8)$$

Remembering that V_t/T is the patient's minute volume and that the measurements of Proctor and Hardy (1949) have shown that the duration of inspiration (T_i) is usually rather less than half the respiratory period (T) it is evident that the flow of fresh gas must be at least rather more than twice the minute volume of the patient.

If assumption 2 is modified to take account of the fact that the expiratory valve will not close until some finite time, T_v, after the start of inspiration, then it can be shown that equation (7) is modified to

$$F_a \geqslant (V_t - V_c)/(T_i + T' - T_v/2) \ldots . (9)$$

As in system A, however, this represents only a very small change in the criterion, since T_v will be only about one-tenth of T.

It is more difficult to determine what will happen if assumption 3 is modified to take account of the increase in pressure drop across the valve which accompanies an increase in flow through it. After the valve has just opened the pressure in the system will increase as the flow through the valve increases and consequently the volume of the bag will increase. If the pressure-flowrate characteristic of the valve has a gentle slope (that is, large flows can be passed for small increases of pressure above the opening pressure) only a small extra volume, including some expired gas, will enter the bag. Depending on the nature of the breathing pattern, some of this volume may still reside in the corrugated tube at the start of inspiration and so be rebreathed. If, however, the characteristic has a steep slope an appreciable volume would enter the bag, and to prevent this containing any "contaminated" expired gas it would be necessary to ensure that the bag reached its maximum volume early in expiration, before the expiration contained any gas which had been in contact with the alveoli of the lungs. It can be shown that this can be achieved if the valve first opens very soon after the start of expiration—in other words, if the fresh gas supplied by the machine during inspiration is almost as large as the patient's tidal volume.

Thus when account is taken of the effect of the various errors introduced by assumptions 2, 3 and 5 it seems probable that rebreathing of contaminated gas will be almost, if not quite, eliminated provided that the supply of fresh gas is at least equal to twice the patient's minute volume.

SYSTEM C

Expiratory valve, supply of fresh gases and reservoir bag, all close to face mask. (No corrugated tube.)

From figure 1 it is apparent that system C can be regarded as a limiting case of either system A or B in which the length of the corrugated tubing has been reduced to zero. The flow conditions of system A will be seriously altered when the length of the corrugated tube approaches zero since it can then no longer act as a depot in which the early part of expiration can temporarily reside, to be driven out of the expiratory valve, later in the expiratory phase, by fresh gases. In system B, however, the tubing merely forms an extension of the reservoir bag so that the conditions for the elimination of rebreathing in system C are the same as those in system B. If, however, any rebreathing does occur, the way in which the concentration of carbon dioxide builds up in the inspired air may well be different since mixing of each expiration with the gas in the bag will occur more efficiently in this system than in system B.

SYSTEM D

Supply of fresh gases close to face mask, separated by corrugated tube from reservoir bag and expiratory valve.

In this system during expiration fresh gas and expired gas will flow together, backwards along the corrugated tube, initially into the bag and later, when the bag has attained its critical volume, V_c, out through the expiratory valve. During inspiration, fresh gas will flow directly to the patient at a rate F_a, the remainder of the patient's inspiratory requirements being drawn along the corrugated tube from the bag.

The conditions in this system are clearly rather different from those in the three systems already considered. Any expired gas which enters the corrugated tube and is subsequently inspired will undoubtedly have been in contact with the alveoli of the lungs since it was derived from the last part of expiration. Thus, for the complete elimination of rebreathing, *no* gas from the previous expiration must be allowed to enter the lungs. The only condition under which gas may be drawn from the corrugated tubing during inspiration is if between the end of expiration and the beginning of inspiration there is a pause of duration, say T'', during which a volume of fresh gas, $F_a T''$, will accumulate in the right-hand end of the corrugated tube.

Then this volume, plus that supplied by the anaesthetic machine, must be not less than the tidal volume.

That is $\quad F_a T'' + F_a T_i \geqslant V_t$

or $\quad F_a \geqslant V_t/(T_i + T'') \ldots\ldots\ldots (10)$

Since T'' is rarely more than a small fraction of T, the period of the respiratory cycle, this condition is approximately the same as that given by equation (8). Here it will hold true whatever the nature of the expiratory flowrate pattern (since T'' may be put equal to O if necessary), but it may be rendered false by certain types of inspiratory flowrate patterns. If $T'' = O$ then no gas must be drawn from the corrugated tube during inspiration. If the inspiratory flowrate pattern is a perfect square wave, then the assumption made above ($F_a T_i \geqslant V_t$ when $T'' = O$) is justified, since the inspiratory flowrate will be constant and not greater than F_a during inspiration. However, if for the same tidal volume the inspiratory flowrate pattern is at all "peaky" some small volume of gas will at some stage during inspiration be drawn from the corrugated tube to be replaced by an equal volume of fresh gas from the anaesthetic machine towards the end of inspiration. If there is an appreciable expiratory pause ($T'' \neq O$) there would probably be a sufficient volume of fresh gas in the right-hand end of the corrugated tube to act as a buffer against this effect.

In this system there is no need to make assumptions 2, 3 and 5. It can be stated that rebreathing will be eliminated, providing the inspiratory flowrate pattern is not too "peaky", if the supply of fresh gas is at least equal to some value slightly greater than twice the patient's minute volume.

SYSTEM E

Supply of fresh gases close to face mask. Open length of corrugated tube. No reservoir bag or expiratory valve.

The conditions in this system are little different from those in system D except that during inspiration some fresh air may be drawn into the left-hand end of the tube and during expiration both expired gases and fresh gas from the machine will pass backwards along the corrugated tube straight out into the air. Assuming that wide bore connectors and tubing are used, the resistance of the system is very low. Therefore, the inspiratory flowrate pattern will be appreciably "peaky", but there will be an appreciable expiratory pause (Proctor and Hardy, 1949) so that the conditions for the elimination of rebreathing will be approximately the same as in system D.

Another method of eliminating rebreathing in this system is to use a very short length of corrugated tube. Suppose there is a definite pause, of duration T'', between the end of expiration and the start of inspiration. Then a volume, F_aT'', of fresh anaesthetic gases will enter the corrugated tube during this time. If the volume of the tube is no greater than this, then no rebreathing can occur (assuming that the expired gases are swept away from the end of the tube by draughts) However, if advantage is taken of this fact, the anaesthetic mixture will be diluted by fresh air unless F_a (T_1 + T'') is at least equal to V_t. That is to say, that the flow of fresh gases must be at least equal to about twice the patient's minute volume.

Thus, if there is an expiratory pause, rebreathing can be eliminated in this system by using a length of corrugated tubing whose volume is no greater than the product of the duration of the expiratory pause and the flowrate of fresh anaesthetic gases, but the anaesthetic mixture will then generally be diluted by fresh air. If it is desired to avoid this dilution as well as eliminate rebreathing, then the flowrate of fresh gases must be at least equal to twice the patient's minute volume and then the length of the corrugated tubing is of little consequence except from the point of view of resistance.

CONCLUSIONS

From these results it is apparent that system A has a marked advantage over the others from the point of view of economy of gases (assuming that it is desired to eliminate rebreathing). On the other hand, system E has a marked advantage over the others from the point of view of resistance to breathing—all the other systems involve the use of an expiratory valve which imposes an appreciable resistance to expiration, particularly when it is passing a large flow (Mapleson and Mushin, 1954) as it will be with the high flowrates of anaesthetic gases required to eliminate rebreathing in systems B, C, and D.

SUMMARY

The flow of gases in five different semi-closed anaesthetic systems is examined theoretically. The minimum flowrate of fresh anaesthetic gases required to eliminate rebreathing is determined in each case.

The results may be summarized by saying that rebreathing has probably been eliminated if the flow of fresh gases is at least equal to the patient's minute volume in system A (fig. 1) and at least equal to about twice the minute volume in systems B, C, D, and E. Rebreathing can also be eliminated in system E with a smaller flow of gas if there is an expiratory pause and if the volume of the corrugated tube is no greater than the product of the duration of this pause and the flowrate of fresh anaesthetic gases, but then the anaesthetic mixture will generally be diluted with fresh air.

ACKNOWLEDGMENTS

The author's thanks are due to Professor William W. Mushin for encouragement and to Miss June Williams for the figures

LIST OF SYMBOLS USED

f_r = volume flowrate of gases to or from the patient.
F_a = volume flowrate of fresh gases from the anaesthetic machine.
F_m = patient's minute volume.
n = number of respiratory cycles per minute.
T = duration of one complete respiratory cycle = $T_1 + T_2$.
T_1 = time from the start of one inspiration to the end of the same inspiration.
T_2 = time from the end of one inspiration to the start of the next inspiration
T_3 = duration of the period at the beginning of inspiration in which $f_r < F_a$
T_4 = time from the start of inspiration to closure of the expiratory valve (when taking account of the real valve characteristic).
T' = time from the end of inspiration to the opening of the expiratory valve.
T'' = time from the end of one expiration to the start of the next inspiration ("expiratory pause").
V_o = volume of reservoir bag when the pressure inside it is equal to the opening pressure of the expiratory valve.
V_1 = volume of reservoir bag at the end of inspiration.
V_2 = volume of reservoir bag at the beginning of inspiration (when taking account of the real valve characteristic).
V_r = volume inspired by the patient during the period T_4.
V_d = deadspace of patient plus face mask.
V_t = patient's tidal volume.

CORRESPONDENCE

Tracheal intubation in trauma

Sir,—The article by Nolan and Parr[1] depicted in-line cervical stabilization and cricoid pressure during tracheal intubation in the trauma patient (fig. 2). In figure 2, in-line cervical stabilization is demonstrated as if it were a single-handed technique. It is accepted practice, however, to perform this manoeuvre as a double-handed technique (although we are sure this is the effect of the line drawing rather than the authors' practice). The same figure also depicted single-handed cricoid pressure. There has been some controversy in the literature regarding the practice of cricoid pressure in the trauma patient with potential cervical spine injury. Some authors have claimed that there is no difference in the view obtained of the larynx[2] whereas other assert that bimanual cricoid pressure enhances the view of the larynx.[3] There is debate on the safety and efficacy of either technique on the stability of the cervical spine during tracheal intubation.

In a recent investigation,[4] Gabbott examined movement of the cervical spine with single-handed cricoid pressure in subjects in whom the trachea was intubated, although unfortunately he did not compare it with bimanual cricoid pressure. In the discussion that follows, he makes recommendations that we would agree with in the management of the potentially unstable cervical spine during intubation. We would suggest that if a hard cervical collar (particularly the two-piece collar) has been applied before tracheal intubation, then the posterior piece provides adequate support for the back of the neck and single-handed cricoid pressure may then be applied. Indeed, to remove the collar may risk additional movement of the cervical spine.[5] If a hard collar is not in place then bimanual cricoid pressure is probably the safer practice.

5. Morley A. Cervical spine control during pre-hospital tracheal intubation of trauma victims. *Anaesthesia* 1995; 50. 661.

Sir,—The technique of manual in-line stabilization (MILS) is indeed a two-handed procedure. The line drawing in our article was made from a photograph published previously.[1] Unfortunately, the right forearm and hand of the person providing MILS is not visible from the direction the photograph was taken. Furthermore, the posterior half of the Philadelphia collar is barely visible in the original photograph and has been omitted from the drawing. The precise procedure has been described previously[1]: "an assistant applies manual in-line stabilisation by grasping the mastoid processes, whereupon the front of a semi-rigid collar can be removed safely". If the patient is fitted with a single piece collar it is our practice to undo it at the front (when MILS has been applied) and tuck the anterior section out of the way under the patient's right shoulder. We agree that this prevents the risk of moving the neck while attempting to remove the collar and may offer some posterior support during application of cricoid pressure.

While in theory two-handed cricoid pressure may be safer then one-handed in the presence of a potential cervical spine injury,[2 3] there is no evidence to support this. Furthermore, one-handed cricoid pressure allows the assistant to use the other hand to help the intubator. If intubation is likely to be very difficult (in the presence of severe maxillofacial injury, for example), it may be wise for a surgeon to apply cricoid pressure with his left hand; in the event of inability to intubate the trachea he is then well positioned to immediately perform a surgical cricothyroidotomy. It is likely that the precision of cricoid pressure applied is more important than whether a one- or two-handed technique is used. Vanner and colleagues have shown recently that the view at laryngoscopy may be improved if cricoid pressure is applied in an upward and backward direction.[4]

In summary, wherever possible it would seem wise to use the posterior section of a semi-rigid collar to provide support to the potentially injured cervical spine during application of cricoid pressure. We must await further data to determine if, in the absence of a collar, two-handed cricoid pressure is more beneficial than the one-handed technique.

Calculating catecholamine extraction from plasma

Sir,—We would like to comment on the article by James and colleagues.[1] They measured flow rate and catecholamine concentrations in the inflow and outflow blood across several organs, and calculated the extraction ratio (ER) of catecholamines in each organ. They reported that the ER of norepinephrine by the porcine liver was 30 ± 11%. However, it has been established that every organ, with the exception of the brain, not only extracts catecholamines from plasma but also releases catecholamines into plasma.[2] This implies that plasma catecholamine concentration is determined by the balance between its spillover into the systemic circulation from sympathetic nerve terminals and its disposal from the circulation. Therefore, the ER values obtained by James and colleagues cannot be considered real, but only as "net" values.

To obtain a true ER by an organ, an isotope dilution method should also be performed. For example, Åneman and colleagues have combined a conventional and isotope dilution method, obtaining an ER for norepinephrine in the human liver of 86 ± 6%.[3] Although species difference should be taken into account, there is a possibility that James and colleagues have underestimated the ER values in each organ. Whatever the existing methodological problems, we agree with the hypothesis that the liver plays an important role in clearing plasma norepinephrine, especially in restricting the amount reaching the systemic circulation from the mesenteric organs.

Sir,—We are in full agreement with the comment of Irita and Takahashi that our measurements reflet *net extraction ratio* of catecholamines and not *"true"* extraction ratio. This distinction was, in fact, referred to briefly in our article. Our interest in this study was to establish the effects of various organs on circulating plasma catecholamine concentrations in response to hepatectomy and we were therefore interested primarily in the net value. Although we are aware of the isotope studies and their importance in terms of establishing the *real* rate of removal of catecholamines by any organ, we are happy that the *net* effect which we examined was appropriate for our study. We concur with the observation by these authors of the importance of the liver in catecholamine metabolism.

Extradural buprenorphine and breast feeding after Caesarean section

Sir,—I would like to comment on the article on extradural buprenorphine and breast feeding after Caesarean section by Hirose, Hosokawa and Tanaka.[1] In this study, the authors administered 0.25% bupivacaine 0.7 ml h^{-1} or bupivacaine and buprenorphine 12 μg ml^{-1} in the control study and groups, respectively, as a continuous infusion for 3 days. They also administered diclofenac suppositories 25 mg for additional analgesia. I am curious why the authors did not choose patient-controlled analgesia (PCA).[2]

Another intriguing point is why the patients were kept in hospital for 11 days. It seems that the authors had no concern as to the financial and psychological costs of this prolonged hospitalization.

The authors published a study with similar results in 1996 in *Anesthesia and Analgesia.*[3] Despite the fact that the authors used spinal anaesthesia in addition to continuous extradural analgesia in their previous study, the results were similar.

The amount of breast milk is dependent on factors such as quantity of glandular tissue in the breast, nutritional status of the mother and the psychological status of the mother.[4] I assume that the psychological burden on the patients hospitalized for 11 days was significant. The authors seemed to have ignored this issue.

On reviewing their references, it noteworthy that there is a lack of studies on this subject.

3. Hirose M, Hara Y, Hosokawa T, Tanaka Y. The effect of postoperative analgesia with continuous epidural bupivacaine after cesarean section on the amount of breast feeding and infant weight gain. *Anesthesia and Analgesia* 1996; 82: 1166–1169.
4. Pierse P, Aerde JV, Clandinin MT. Nutritional value of human milk. *Progress in Food and Nutritional Science* 1988; **12:** 421–427.

Sir,—Dr Celebioglu questioned why we did not use patient-controlled analgesia (PCA) in our studies.[1,2] This was because we did not have enough PCA pumps for all of our subjects.

Dr Celebioglu also noted the prolonged hospitalization after Caesarean section in our studies,[1,2] which was the key point in obtaining our data on the total weight of breast milk. The length of hospitalization after Caesarean section was 12 or 13 days in our studies, which is longer than that reported in other countries.[3] Similarly, mean duration of hospitalization after laparoscopic and open cholecystectomy was reported as 11.4 and 35.5 days in Japan,[4] but only 1.8 and 2.8 days in Sweden.[5] In Japan, doctors and related professionals are well aware of the fact that postoperative hospital stay is relatively prolonged compared with other nations. This prolonged hospitalization is partly a result of the Japanese health care system. It may have affected breast feeding psychologically after Caesarean section, but it had no effect on between-group evaluation of our data, all of which were obtained during the same length of hospital stay.

We appreciate that Dr Celebioglu compared our two studies. Postoperative analgesia was performed with or without extradural bupivacaine in the first study,[1] and in the second study it was performed with extradural bupivacaine or extradural bupivacaine plus buprenorphine.[2] After we reported that extradural bupivacaine after Caesarean section improved breast feeding,[1] many clinical researchers asked us about the effect of extradural opioids on breast feeding. The second study was designed to evaluate the effect of extradural buprenorphine on breast feeding after Caesarean section. Taken together, breast feeding with postoperative extradural bupivacaine and buprenorphine was suppressed to the same level as that without extradural analgesia after Caesarean section.

Why the Y?

Sir,—Perhaps it is a sign of secular times but, in searching for the essential J. Y. Simpson, and putting a modern "spin" on his life, Rae and Wildsmith[1] have missed the importance of religious faith to the era, the environs and his life.[2] It was a life lived during one of turmoil in Scotland's theological history. The defence of anaesthesia, on biblical textural grounds, is all the more poignant for the fact that Simpson was active in the disruption of the Church of Scotland in 1843 and is identified with the more radical, and fundamental break-away, Free Church.[2,3] It may sound pious nowadays, but Simpson's own analysis of his worth was that his greatest discovery, in a lifetime of them, was that "I have a Saviour".[4]

The acquisition of the sobriquet,[1] "Young", intrigued a generation of assiduous anaesthesia historians. Armstrong Davison stated that "... and the story how and why he assumed his second name, "Young", indicates his forceful and tactless behaviour".[5] W. S. Sykes devoted much of a chapter to the rumour, confirming that the whispers of the adoption of a middle name, with which Simpson had not been baptized, were true.[6] Sykes concluded it was an affectation adopted, when at the age of 28 yr and very conscious of his youth, Simpson had the temerity to apply for the Chair of Midwifery in Edinburgh. It is a mystery as to why it ever became an issue and subject of rumour that Armstrong Davison's readers would have known all about.[5] Armstrong Davison's "story" has gone to his grave. Or has it?

2. Shepherd JA. *Simpson and Syme of Edinburgh*. Edinburgh: E&S Livingstone Ltd, 1969.
3. Simpson EB. *Sir James Y Simpson*. Edinburgh: Oliphant, Anderson, and Ferrier, 1896; 127.
4. Gardner R. A Christian physician's greatest discovery: Sir James Young Simpson 1811–70. *Journal of the Christian Medical Fellowship* 1992; 38: 5–8.
5. Armstrong Davison MH. The evolution of anaesthesia. *British Journal of Anaesthesia* 1960; 32: 141–146.
6. Sykes WS. What's in a name? In: Ellis RH, ed. *Essays on the First Hundred Years of Anaesthesia, vol 3*. Edinburgh: Churchill Livingstone, 1982; 35–42.

Sir,—We thank Dr Conacher for his interest in, and comments on, our editorial. It was produced to indicate why the sesquicentenary celebration in Edinburgh was used to mark Simpson's "whole contribution to medicine" rather than just the anniversary of the first anaesthetic use of chloroform. We did refer to Simpson's "extensive knowledge of the bible" where it was relevant, but deliberately eschewed considering his involvement in the religious controversies of the day; these were not immediately relevant to our theme. In addition, we do appreciate that an *incorrect* reference to such controversy might have produced even more vigorous comment than Dr Conacher's.

The source of the sobriquet "Young" seems self-evident to us. He was the youngest of nine children, born 4 yr after his immediate senior–surely he was neither the first nor the last such child to be nicknamed "Young". The really intriguing aspect is why Armstrong Davison and Sykes were so obsessed with the issue. Both used it to denigrate Simpson, but neither provided any primary source information–very uncharacteristic behaviour for such "assiduous historians". Thus we too would like an answer to Dr Conacher's final question, but we wonder if it is simply the historical equivalent of the "tall poppy" syndrome, precipitated by their clear opinion that Simpson had not been as assiduous as he might in deflecting the credit he was often given for "discovering" anaesthesia.

Propofol in paediatric intensive care: further evaluation is justified

Sir,—We were interested to read the study by Martin, Murthy and Petros[1] suggesting that infusion of propofol may be used safely to sedate critically ill children after cardiac surgery, and support the recommendation by Hatch that larger controlled studies need to be undertaken to develop criteria for its safe use.[2] The ICU at Frenchay hospital admits 60–80 children per annum, mainly after head injury or with other neurosurgical/neurological diagnoses. We believe that continuous infusion of propofol offers advantages in sedating these children, as it allows rapid changes in the level of sedation, facilitating rapid and repeated assessment of the child's level of consciousness and neurological function.

We audited our experience with the use of propofol infusions to sedate children over a 3-yr period.[3] Propofol was infused alone or in combination with an opioid. The maximum infusion rate of propofol allowed was 6 mg kg^{-1} h^{-1}. If this failed to achieve adequate sedation, propofol was discontinued and midazolam was used. No child received propofol if there was evidence of respiratory tract infection, and the infusion was discontinued if the child developed lipaemic serum. There were 158 children admitted, 71 of whom received propofol for sedation, usually in combination with an infusion of morphine (74.6% of children). Median age was 9.5 yr (range 10 months to 15 yr). All children were admitted after head injury or with another neurosurgical/neurological diagnosis, except for three children who were admitted with severe burns.

Median rate of infusion of propofol was 3.1 (range 0.6–6.0) mg kg^{-1} h^{-1} for a median duration of 16 (range 2–149) h. All children were adequately sedated except for two in whom midazolam was substituted for propofol when 6 mg kg^{-1} h^{-1} failed to sedate the child adequately. All children were easy to assess neurologically by simply reducing the rate of infusion of propofol. Median time to extubation after stopping the propofol infusion was 40 (range 10–510) min. No child developed lipaemic serum, unexplained acidosis, hepatic or cardiac failure.

The dose of propofol used was slightly more than the median rate of infusion of 2.1 mg kg^{-1} h^{-1} reported by Martin, Murthy and Petros.[1] This probably reflects the deeper level of sedation required in the management of patients with head injuries or other diseases likely to cause increased intracranial pressure. In every other aspect our experiences were similar. We support the conclusion of Martin, Murthy and Petros that propofol may be used safely to sedate children receiving intensive care provided that the maximum infusion rate is not exceeded. The criteria they recommend for the safe use of propofol in children should be used as the basis of further larger studies evaluating the use of the drug to sedate other groups of critically ill children in addition to the postoperative cardiac surgical population.

Sevoflurane in acute airway obstruction

Sir,—I was interested to read Mostafa and Atherton's report on the use of sevoflurane in patients with difficult airways.[1] They remarked how rapidly deep anaesthesia was achieved, although none of their patients had significant respiratory obstruction.

I recently anaesthetized a 75-yr-old woman with stridor caused by laryngeal carcinoma. She was obese and a heavy smoker. She had refused any procedure under local anaesthesia. After administration of nebulized epinephrine, anaesthesia was induced with sevoflurane in 100% oxygen. Starting at a concentration of 2%, this was increased in increments to 8%. Loss of consciousness was rapid (less than 1 min). After 2 min, I attempted laryngoscopy, but the patient gagged. A similar incident occurred at 5 min. In the meantime, her airway was becoming increasingly difficult to hold owing to loss of muscle tone in a bulky neck. Finally, after 10 min, laryngoscopy was possible; the vocal cords could be seen and succinylcholine was given. Intubation, however, was unsuccessful and necessitated intervention of the ENT surgeon with a rigid laryngoscope. The improved view allowed intubation with a size 6 tracheal tube.

Deep anaesthesia with sevoflurane was hard to achieve in this situation. It was better than with halothane. Sevoflurane has a lower blood:gas solubility, but is much less potent than halothane. In the case of respiratory obstruction, is potency as important as solubility?

1. Mostafa SM, Atherton AMJ. Sevoflurane for difficult tracheal intubation. *British Journal of Anaesthesia* 1997; 79: 392–393.

Sir,—I was interested to read about the three patients with expected difficult intubation in whom inhalation induction with sevoflurane proved useful in airway management.[1] Since the introduction of sevoflurane in Singapore, I have found this agent to be similarly useful in patients with head and neck tumours presenting for examination under anaesthesia, biopsy or for surgery. Two cases may be worth mentioning.

An obese 56-yr-old woman presented with a massive multinodular goitre for thyroidectomy. Awake fibreoptic intubation proved impossible because the patient became distressed, uncooperative and hypoxic during the attempt. After inhalation induction with sevoflurane up to 6% in 100% oxygen, direct laryngoscopy was undertaken to reveal a grade 4 larynx.[2] Blind passage of a gum elastic bougie into the trachea was suggested by the patient's cough and confirmed by capnography when a tracheal tube was successfully "railroaded".

A 48-yr old man presented with a nasopharyngeal tumour for examination under anaesthesia and biopsy. After inhalation induction of anaesthesia with sevoflurane in oxygen, direct laryngoscopy was performed. A haemorrhagic tumour was found occluding the laryngeal inlet. Intubation was not attempted and spontaneous ventilation was maintained using sevoflurane in oxygen while the surgeon proceeded to perform a tracheostomy.

I agree with Mostafa and Atherton that sevoflurane has replaced halothane for inhalation induction of anaesthesia in the management of the difficult airway. I have found no advantages in the use of nitrous oxide in this particular situation.

P. C. Ip-Yam

2. Cormack RS, Lehane J. Difficult tracheal intubation in obstetrics. *Anaesthesia* 1984; 39: 1105–1111.

Sir,—Thank you for the opportunity to reply to the letters of Dr Board and Dr Ip-Yam. Our interest in using sevoflurane in the management of patients with difficult airways was not how *rapidly* it achieved anaesthesia, albeit important, as much as how *easily* anaesthesia was accomplished and how the airway was maintained without difficulty. It is pertinent to state that our experience is not limited to the three cases we described. Our impression is supported by Dr Ip-Yam's letter describing the use of sevoflurane in the management of children and adults with difficult airways. Our experience is also corroborated by the recent report of Frerk and Tordoff[1] in which they described the management of three patients with difficult airways. Furthermore, and perhaps most important, the low blood:gas solubility of sevoflurane implies that, if difficulty is encountered with induction, it should be easier and quicker to lighten anaesthesia and wake the patient. This is the great advantage of inhalation induction.

Dr Board unfortunately raises the wrong question. In certain cases of stridor, such as in the patient he described, the choice for securing the airway should lie between awake intubation and tracheostomy under local anaesthesia, *not* the potency or solubility of a general anaesthetic agent. In our view, such a patient should not be anaesthetized before securing the airway. General anaesthesia may reduce muscle tone which can lead to complete airway obstruction. But sometimes our approach is not feasible because of lack of cooperation of the patient, or because of lack of an anaesthetist skilled in awake intubation.[1] In addition, the use of halothane may be contraindicated, as in the cases we described. In these circumstances the use of sevoflurane for inhalation induction may offer the safest solution. As Dr Board had not used halothane when he encountered difficulties it would be impossible for anyone to judge if it or sevoflurane was the better agent.

In conclusion, we would maintain that inhalation induction with sevoflurane is a useful technique in the armamentarium of anaesthetists for the management of patients with difficult airways.

Anaesthesia for surgery of emphysema

Sir,—Dr Conacher's comprehensive review article on anaesthesia for surgery for emphysema[1] is marred by the advocation of extradural analgesia as the only vital analgesic technique.

Paravertebral analgesia blocks not only the intercostal nerves but also the sympathetic chain and posterior primary rami, providing equally effective postoperative analgesia in addition to inhibiting the stress response to surgery.[2] It has fewer side effects than extradural analgesia,[2,3] and is safer and technically easier to perform.[4] By producing only unilateral block, paravertebral analgesia avoids hypotension and thus the need to administer excessive i.v. fluids or vasopressors to maintain tissue perfusion.[3]

Balanced analgesia, by blocking both peripheral and central pain mechanisms, has also been recommended in the form of preincisional paravertebral block, opioid premedication, preoperative non-steroidal anti-inflammatory drugs and postoperative continuous paravertebral block.[2] It provides effective postoperative analgesia and minimizes the loss in pulmonary function seen after thoracotomy.[2]

2. Richardson J, Sabanathan S, Mearns AJ, Evans CS, Bembridge J, Fairbrass M. Efficacy of pre-emptive analgesia and continuous extrapleural intercostal nerve block on post-thoracotomy pain and pulmonary mechanics. *Journal of Cardiovascular Surgery* 1994; 35: 219–229.
3. Matthews PJ, Govenden V. Comparison of continuous paravertebral and extradural infusions of bupivacaine for pain relief after thoracotomy. *British Journal of Anaesthesia* 1989; 62: 204–205.
4. Berrisford RG, Sabanathan S. Direct access to the paravertebral space at thoracotomy. *Annals of Thoracic Surgery* 1990; 49: 854.

Sir,—I would agree with Dr Lafrenière that paravertebral block, balanced with opioids and non-steroidal anti-inflammatory drugs (NSAID), is one of several options for analgesia that could be justified, on the grounds suggested, for patients whose pulmonary condition renders them suitable for routine thoracotomy or thoracoscopy. However, for patients with bilateral emphysematous conditions, verging on respiratory failure, undergoing lung transplantation, volume reduction surgery or non-thoracic surgery, the technique does not have a track record and would not be viewed as best practice.

For the last group of patients (those most likely to be encountered by the non-specialist in the middle of the night) the risk of pneumothorax[1] in a vulnerable population would have to be added to the dangers caused by the balancing of analgesia with NSAID. The use of non-essential drugs that can precipitate renal failure in the presence of low volume urine production are viewed askance by those caring for patients in whom one organ is already failing. These patients may require toxic immunosuppressants, and a vital element in their recovery is fluid restriction. The international consensus, from the review I undertook, is that extradural analgesia is the gold standard and I would not, at this time in the evolution of the third age of thoracic anaesthesia,[2] suggest anything less except in failure to achieve that standard. In which case, there are safer options than paravertebral block and NSAID.

Suboptimal use of inhaled aerosol therapy during mechanical ventilation in intensive therapy units in the UK and Ireland

Sir,—Aerosol delivery of nebulized drugs appears less efficient than in patients breathing spontaneously and is highly dependent on the method used.[1,2] To examine the pattern of use of aerosol drug therapy during mechanical ventilation in intensive care units in the UK and Republic of Ireland, and to establish how frequently proven methods of optimizing drug delivery were used, a postal questionnaire was sent to consultants in those intensive care or high dependency units listed in the 1995 Directory of Emergency and Special Care Units in the UK and Ireland, between March and October 1995. In the event of no response, after 3 months a reminder letter was sent. The questionnaire enquired about the size and type of the intensive care unit and number of patients treated. Details were sought about the use of aerosol therapy during mechanical ventilation, including drugs, ventilators and methods of nebulization used.

Responses were received from 175 of 213 (82%) units. All had used aerosol drug therapy during mechanical ventilation within the last year and 168 units had used it within the previous month. Drugs used in the previous month included beta$_2$ adrenoceptor agonists (168 units), anticholinergic drugs (140 units), corticosteroids (57 units), antibiotic or antiviral agents (18 units), prostacyclin (13 units) and surfactants (three units). Most (162) units used jet nebulizers, while the simpler, less expensive and possibly more efficient[1] metered dose inhalers were used less often (34 units). Although very efficient,[3] ucspasonic nebulizers were used rarely (six units).

Table 1 Numbers (%) of units using methods which enhance aerosol delivery during mechanical ventilation. *In units who administered these drugs within the past year

Method of improving delivery	Users (% responders)	Non-users	No response
Jet nebulizers (162 units)			
Placement on inspiratory limb of ventilator system	43 (27%)	115	4
Placement 10–30 cm from Y-piece on inspiratory limb	8 (5%)	150	4
Use of spacer	5 (3%)	157	0
Use of ⩾5 ml nebulizer solution	66 (43%)	89	7
Use of inspiratory phased jet nebulization	67 (41%)	95	0
Interruption of humidification	31 (22%)	109	22
Adjustment of ventilatior settings	46 (29%)	114	2
Nebulizer apparatus removed between use	153 (94%)	9	0
Metered dose inhalers (34 units)			
Use for administering beta$_2$ agonists*	27 (79%)	7	0
Use for administeing anticholinergic drugs*	20 (59%)	14	0
Use for administering corticosteroids*	20 (38%)	14	0
Placement on inspiratory limb of ventilator system	13 (38%)	21	0
Placement 10–30 cm from Y-piece on inspiratory limb	2 (6%)	32	0
Use of spacer	7 (21%)	27	0
Interruption of humidification	6 (21%)	22	6

Methods of enhancing aerosol delivery were used infrequently (table 1). Most units did not position the nebulizer on the inspiratory limb of the breathing system and few used spacers, even though combining these methods may double aerosol delivery to the patient.[1,4] Less than 50% of the responding units used a high drug solution volume in jet or ucspasonic nebulizers, even though delivery may be doubled by increasing the volume of the nebulizer solution from 3 to 6 ml.[5] Most units did not adjust ventilator settings during nebulization and may thus have inadvertently altered the conditions of ventilation, including respiratory minute volume.[1] Discontinuing humidification during aerosol administration improves delivery[2] but was performed infrequently. Most units removed nebulizer apparatus from the breathing system when not in use, which is good practice as it reduces the risk of bacterial contamination.[1]

In spite of the drawbacks in using a postal survey to study the management of patients, we believe the results are a valid reflection of recent practice in the UK and Ireland as the response rate was high. It showed that aerosol drug therapy is used often during mechanical ventilation but the methods used are suboptimal and could easily be improved by some simple modifications. The British Thoracic Society has recently issued guidelines on nebulizer use during mechanical ventilation.[6] Adoption of these guidelines will improve aerosol drug delivery to patients undergoing ventilation in intensive care units, and this is expected to improve the effectiveness of drugs administered by this route.

BOOK REVIEWS

Critical Care Management. Case Studies: Tricks and Traps. G. R. PARK AND M. R. PINSKY (editors). Published by WB Saunders, London. Pp. 303; indexed; illustrated. Price £29.95.

This book is a collection of 51 case reports covering 11 different areas of critical care, including organ failure, obstetric critical care, drug interactions and sepsis. The reports are written by 35 experts from the UK, USA and Australia.

All of the case reports have the same format. A case is described where some aspect of the care has been less than optimal because the physicians involved have fallen into a "trap", which the editors describe as a situation where a logical plan of diagnosis and treatment was applied, but was inappropriate in the particular circumstances described. Various "tricks" are then described, clinical signs, tests and manoeuvres, which would have helped to avoid the "trap". A brief paragraph on follow-up and a few key references complete the report.

This format makes the book very interesting to read. Knowing there is some aspect of the care provided that is less than perfect in each case, you read the report trying to spot the trap, and making comparisons with your own practice and what you would do in the same circumstance. The traps range from the very obvious to some fairly subtle points, and cover a wide range of critical care problems. The tricks sections are in effect discussions of the cases, and these are generally well written and focused.

In America there are far more critical care beds available, and therefore physicians are able to admit less severely ill patients than in the UK. This is apparent in the cases selected for this book; several of the patients described would not be seen commonly in an intensive care unit in the UK, and would be managed on the ward or coronary care unit. This gives the book a broader scope than is apparent from the title, as it covers both critical care and acute medicine. Transatlantic differences in patient management are also apparent, in particular with respect to the use of pulmonary artery catheters. As this is a book of case reports, the wide range of conditions and treatments resulting from the multinational authorship add greatly to the interest of the book.

The book has an international authorship and distribution, and the editors have been careful to ensure laboratory and other data are given in both SI and non-SI units. A comprehensive list of abbreviations and normal laboratory values is included in an appendix.

My only criticism of the book concerns the section on increased intrathoracic pressure where the theme of auto-PEEP occurs many times. Otherwise there is little overlap between the cases described.

This is definitely a book that should be read, rather than a reference book. Although it will be of great interest to the trainee, even seasoned intensivists will glean many useful nuggets of information. I would recommend it to all physicians involved in intensive care.

J. D. Young

Anaesthesia Review–13. L. KAUFMAN AND R. GINSBURG (editors). Published by Churchill Livingstone, Edinburgh. Pp. 330; indexed; illustrated. Price £32.50.

This is the latest in a long and well known series of reviews by the same editors; 27 contributors opine in 17 chapters, with Dr Kaufman penning three of these. The origin of these contributors suggests a sad view of British anaesthesia–no anaesthetist living north of a line drawn between Southampton and Cambridge has contributed to this book. With such a large number of authors, consistency of style is difficult to achieve. The chapters vary in both style and readability from the exceptional to the abysmal.

The relevance of the brief review of the first ether anaesthetic given at University College Hospital is not obvious. It is a well worn story, albeit well told, but reprinted from an earlier edition in the series and singularly out of place in a review of modern medical practice relevant to anaesthesia–151 yr on.

Dr Kaufman introduces the real "meat" of the book with "medicine relevant to anaesthesia", with 138 references providing support for his contribution. "Cocaine" merits three sentences in the section on the cardiovascular system but avoids any reference to typical therapeutic doses to compare against the tacit reference to illicit abuse–not helpful when the latter is better covered specifically later in the book.' Similarly, under a complete section on "sickle cell", although reference is made to a review of sickle cell crisis elsewhere, the six sentences in this section would not help in anaesthetizing a sufferer of the disease. Under the "miscellaneous" heading, a puzzling sub-section entitled "antiemetics" refers to work on the effect of ranitidine and omeprazole on gastric emptying, but omits to mention emesis *per se*.

The chapter on "renal physiology" was much more concise and obviously useful; of the 45 references, several were from 1995. Physicians (hepatologists?) from Birmingham provided a comprehensive update of the "virology of hepatitis", which is well worth reading even if only to emphasize the need to avoid complacency when dealing with body fluids. A particularly useful feature here is the "key points", something which reappears inconsistently throughout the book.

Thyroid storm is covered well in the next chapter on "thyroid disorders" (one has always been wary of this). Perhaps, though, a comparison with the diagnosis of malignant hyperpyrexia (MH) would have been helpful when MH may occur in a typical district hospital only once in 10 yr, with thyroid storm even less frequently. There was surprise that more than 20 yr after the adoption of the Systeme International, there was reference to milligrams of calcium in serum (on page 79), incomprehensible to many in the UK.

In the preface, the editors extol the importance of an understanding of "ion channel receptors" in the modern practice of anaesthesia. Unfortunately, comprehension was not aided by Dr Gibb's erudite discourse on the subject. While this may be a learned treatise, it did nothing to enlighten with its use of unfamiliar terms and unexpanded abbreviations. What are metabotropic receptors? AMPA receptors? and is $GABA_A$ anything to do with GABA or gamma amino butyric acid? Hiding in this jungle of a chapter is, however, a superb piece on neuromuscular transmission

"Intravascular monitoring" provided a rare view on both the history and developments in the pipeline, but "euthanized"' sheep were an unnecessary abuse of English!! Chapters on the "laryngeal mask airway" and "cardiopulmonary resuscitation" were well presented and salient, the former ending with the "key points", while the latter a section of "conclusion". Drs Matta and Menon from Cambridge provide two chapters on "management of acute head injury" with "key points" for the idle! The 38 pages are well used. However, each chapter had its own list of references, 14 being duplicated (one list of references, in correct order (Martin before Matta and Marx) would have been more efficient).

"Parenteral nutrition" is well covered and followed appropriately by a chapter on "extravasation" of parenteral nutrition fluid and other drugs. A whole chapter devoted to a common occurrence among anaesthetist practitioners was apposite. The list of (relatively) safe drugs to extravasate was also useful.

"Substance abuse" provides a parents' as well as practitioners' walk through the life and death associated with "cutting", "bodypacking", "Ecstasy", "Adam", and "Eve" and much more. Essential reading for those in contact with teenagers and their culture. Again, following on from one cause of psychiatric disturbance comes a well placed chapter on the "pharmacology of psychiatric illness". Here the reversible inhibitors of monoamine oxidise A (RIMA) and selective serotonin inhibitors (SSRI) are placed in context, especially in respect of anaesthesia, practitioners of which took a long time to come to terms with the original MAOI class of drugs.

The book finishes with two (two?) updates, both from Dr Kaufman. These are easy to read and well chosen.

In summary we have something of a "curate's egg" of a book. There is no doubt that the good parts outweigh the bad. Despite all the caveats, I commend it strongly as a good value addition to the bookshelf of both the individual and departmental libraries.

VOLUME 80, No.3 MARCH 1998

EDITORIAL I

Diaphragmatic dysfunction: an outmoded concept

The expression "diaphragmatic dysfunction" is a mellifluous phrase used when considering the respiratory changes associated with major surgery.[1–5] A recent editorial in this journal concerning the effects of laparoscopic cholecystectomy[6] discussed inhibition of diaphragm function, modified breathing patterns and changes in the abdominal contribution to breathing attributed to reflex diaphragmatic inhibition: all of these concepts have been considered to represent diaphragmatic dysfunction. However, some articles have voiced muted doubts about the concept,[7–9] which I believe is now sufficiently threadbare to require that the expression be used rarely, if at all, when we consider changes in respiratory pattern after abdominal surgery.

The expression was first used by Ford and co-workers in an article entitled "Diaphragm function after upper abdominal surgery in humans".[10] They applied the theory that diaphragm contraction and descent during inspiration not only generates a decrease in pleural pressure (Ppl), but also an increase in abdominal pressure (Pab). In contrast, if an inspiration is generated by the intercostal muscles acting alone, abdominal pressure decreases. This decrease is the same as the decrease in pleural pressure because the diaphragm is inactive and does not establish a pressure difference between the pleural and abdominal cavities. The relative changes in Pab and Ppl should indicate the relative contributions of these inspiratory muscle groups, the diaphragm and ribcage muscles to inspiratory activity.[11] If Pab changed less, relative to the change in pleural pressure during inspiration, then a "dysfunction" of the diaphragm was present. This analysis is confounded when the abdominal muscles are active. Abdominal muscle contraction followed by relaxation can generate relative changes in Pab and Ppl very similar to intercostal activity (fig. 1). The effect of abdominal muscle activity was generally discounted by early investigators.

Studies employing this analysis have used different means of expressing the relative changes in Pab, Ppl and trans-diaphragmatic pressure (Pdi), which is calculated from the two preceding values, thus: $P\text{di} = P\text{ab} - P\text{pl}$.

The most frequent expressions used are Pab/Ppl (which is awkward because the denominator has a negative value) and Pab/Pdi (which is mathematically related, being $1/(1 - P\text{pl}/P\text{ab})$). Most studies reported that the pressure swings were measured from "maximum to minimum" values, irrespective of time, within a respiratory cycle, read from a chart recorder.[10 12–15] However, it is evident from the theory outlined that to provide an accurate indication of muscle contribution to inspiration, the pressure changes compared must be *during the same period of inspiration.* If the measurements include abdominal pressure changes during expiration, caused by abdominal muscle contraction, this affects the "maximum to minimum" estimates.

Ford and co-workers suggested that the changes they reported "may be attributable to diaphragm dysfunction".[10] Further studies followed, with one using the term "diaphragmatic dysfunction" in the title.[14] Such studies also used other indirect measures of diaphragm function, such as the relative motion of the ribcage and abdomen.[16] Ford and co-workers have since reviewed the topic[7] and are now more circumspect with the term "dysfunction", preferring to describe a change from diaphragm to intercostal activity in a review of the extensive animal studies which support reflex inhibition via visceral afferent pathways.

Unfortunately, the term "diaphragmatic dysfunction" is used when other plausible possibilities have been present. These included phasic activity of the abdominal muscles, which can cause abdominal pressure changes in addition to those changes generated by the diaphragm, and also causes of increased ribcage muscle activation.

Abdominal muscle activity

The normal pattern of change in Pab is an increase during inspiration, with a decline during expiration. However, the abdominal muscles often become active in expiration, for example: in exercise; with impedance to inspiration[17]; in patients with obstructive airways disease[18]; and during anaesthesia.[19] Abdominal muscles are also active in patients after surgery: their activity causes an additional phase of increasing abdominal pressure during expiration. This pressure subsides rapidly at the onset of the next inspiration. It can be greater than the pressure change in inspiration, so that the usual increase in pressure associated with inspiration and contraction of the diaphragm can be swamped by a much greater pressure swing induced by abdominal muscle contraction.[20] In the awake subject, this activity may be continuous, but during sleep or airway obstruction, phasic activity during expiration is more common. Early direct observations of abdominal muscle activity after surgery were later supported by studies which showed activity in patients after thoracotomy,[21] cardiac surgery,[8] abdominal surgery[9] and transiently after laparoscopic surgery.[22]

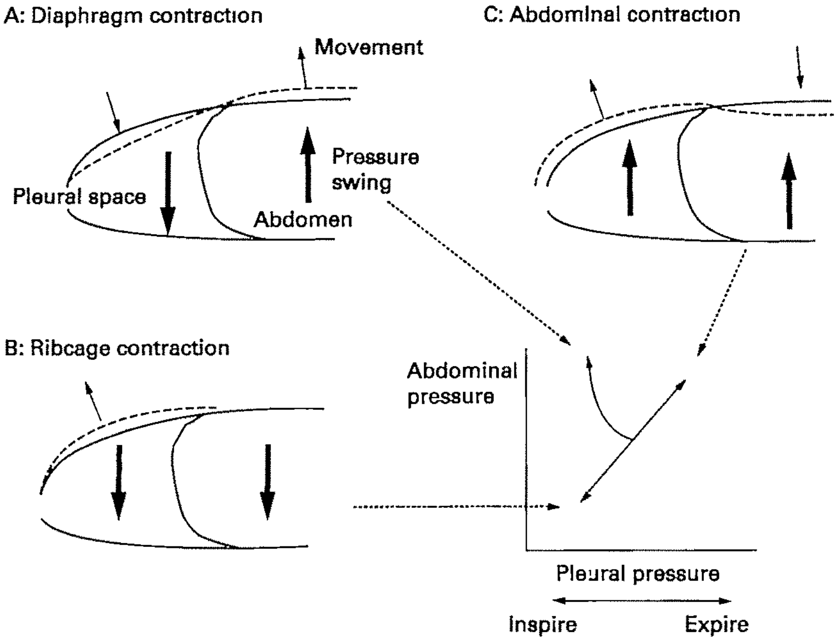

Figure 1 Schematic representation of the actions of respiratory muscle groups. A: Diaphragm contraction: the diaphragm descends, displacing the abdominal wall outwards. Pleural pressure decreases and the ribcage is pulled inwards by the increased pressure difference. B: Ribcage contraction: the ribcage is displaced outwards and pleural pressure decreases. The inactive diaphragm does not create a pressure difference and the abdominal pressure decreases in parallel with pleural pressure. C: Abdominal contraction: the abdominal wall moves in, increasing abdominal pressure and forcing the abdominal contents and the diaphragm cranially. Pleural pressure increases and lung volume decreases (expiration). Relaxation of the abdominal wall reverses these changes.

A plot of abdominal pressure and volume can show how the abdominal muscles are working.[9 22] When abdominal pressure increases as a result of diaphragm action, the abdominal wall moves out: if the increase in pressure has been caused by abdominal muscle contraction, the abdominal wall either does not move (but may change its shape) or moves inwards if the diaphragm does not resist being forced upwards into the ribcage.

Activation of ribcage muscles

The ratio of changes in abdominal and pleural pressure during inspiration reflects the degree of activation of the ribcage and diaphragm. After operation, the predominant effect may be an increase in ribcage muscle action. An increase in the proportion of drive to the ribcage muscles can result for several reasons. If there is an overall increase in drive, such as is common after surgery, then the proportional activation of other inspiratory muscles is likely to increase to a greater extent than that of the diaphragm.[23] Even if overall drive does not increase, changes in airway resistance with sedation can lead to marked increases in ribcage movement,[24] probably from a reflex increase in activity of the ribcage muscles, which are richly supplied with muscle spindles. Nimmo and Drummond found that patterns of pressure changes, consistent with increases in ribcage activity, were significantly related to airway obstruction.[9] Clergue and colleagues[8] concluded that increased ribcage muscle activity and phasic expiratory activity were responsible for the postoperative changes they described, with no convincing evidence of alterations in diaphragm activity. Finally, even with the same drive and relative intercostal activity, abdominal pressure changes are greater, and abdominal movements less, if abdominal compliance is decreased, for example by tonic abdominal activity.[25]

How can dysfunction of the diaphragm be defined and recognized? A simple definition is that a muscle is functioning less well if it fails to generate its normal tension for a given degree of electrical activation. In patients after abdominal surgery, this is not easy to demonstrate. Respiratory frequency increases and tidal volume is reduced after abdominal surgery.[26] Consequently progressive activation of the diaphragm during inspiration is cut short more quickly, and the degree of activation at the end of inspiration is less than that before operation. Simple measures of activity at the end of inspiration are thus of no value in determining changes in diaphragm properties. Changes in electrical activity, such as those reported after extradural block in postoperative patients,[27] could be attributed to changes in respiratory frequency that occur at the same time. When electrical activity was related to transdiaphragmatic pressure, extradural analgesia did not alter the relationship between electrical activity and pressure generated by the diaphragm, despite changes in other "indices of contractility" such as $\Delta Pab/\Delta Pdi$.

In five patients after abdominal surgery, direct maximal stimulation of the phrenic nerves, with measurement of the resultant diaphragmatic pressure, was used to assess any changes in diaphragm contractility. Although this study would have been technically difficult, the results suggested that there was no change in contractility.[13]

The remaining attribute of the concept of "diaphragmatic dysfunction" is of central inhibition of inspiration, caused by visceral pain. Limitation of vital capacity has long been recognized to accompany abdominal surgery, and to be more marked the closer the incision is to the diaphragm. More recently, laparoscopic intra-abdominal procedures have also been recognized to limit maximal inspiration, and this effect is more severe after cholecystectomy than lower abdominal procedures, suggesting that visceral damage is important.[28] The exact neural pathways involved are not clear: extradural anaesthesia can only partly restore vital capacity, and the activity of the diaphragm on maximal voluntary inspiration is more suppressed than "semi-voluntary" maximal manoeuvres such as sniff.[28] There are no data to indicate that inhibition of maximal inspiration is exclusive to the diaphragm.

The concept of "dysfunction" led to interventions to reduce it. Two approaches were investigated. Aminophylline, which can improve muscle contractility in some circumstances, was given to patients after upper abdominal surgery.[15] The example trace in this study shows that considerable abdominal muscle activity was present, with abdominal pressure increasing during expiration and suddenly decreasing at the start of inspiration. Aminophylline abolished this abdominal muscle action, converting the trace to one that resembled the preoperative pattern. Nevertheless, the authors rejected the possibility that abdominal muscle action was responsible for the changes they reported, on the grounds that the pressure swings were similar before and after operation, and suggested that administration of aminophylline improved the index $\Delta Pab/\Delta Pdi$ and thus improved diaphragm function. However, in experimental animals treated with aminophylline, direct measurements of diaphragm length did not show an improvement in diaphragm contractility,[29] and another clinical study found an increase in maximal inspiratory effort that was probably a centrally mediated effect.[2] It appears that aminophylline acts as an analeptic. Even if it were an effective therapy, it is unlikely to prove popular: it has a narrow therapeutic margin, several adverse effects and important interactions with other treatments used in postoperative patients.[30]

If diaphragm dysfunction is caused by reflex inhibition, then extradural block might interfere with the reflex and improve mechanics. Motor block of the abdominal muscles also has a potentially important effect on chest wall movement. Mankikian and co-workers studied the effects of thoracic extradural block to T4 obtained with 0.5% bupivacaine, using $\Delta Pab/\Delta Ppl$ and chest wall measurements.[12] No electrical measurements of abdominal muscle activity were made, but activity was clinically evident in two of the 12 patients. The change in abdominal pressure was measured as "peak inspiratory minus peak expiratory pressure" so the expiratory pressure included contributions from abdominal muscles. Not surprisingly, the main effect of what was probably a large degree of abdominal motor block was a small increase in the abdominal pressure swing, and an increase in abdominal outward movement on inspiration. They concluded that diaphragm function had improved, although the probable abdominal muscle motor block makes this conclusion uncertain. A subsequent study from these workers[27] recognized the problems of expiratory abdominal muscle action and incorporated changes in the measurements of the pressure swings to avoid the expiratory phase. They also measured diaphragm electrical activity and found no evident changes in contractility. Despite paradoxical breathing patterns, where the abdomen moved inwards during inspiration, the electrical activity of the diaphragm persisted. They concluded that the diaphragm was inhibited by visceral pain and that extradural block removed the afferent stimulus causing this inhibition. In fact, the most prominent effects noted were a decrease in respiratory rate, an increase in tidal volume and a greater outward movement of the abdomen, all of which could result from abdominal sensory and motor block.

More invasive studies did not reveal important changes in diaphragm function. Fratacci and colleagues[21] studied the effects of thoracic extradural block in a small number of patients after thoracotomy, in whom sonomicrometre crystals had been implanted to measure changes in diaphragm length. Extradural analgesia did not improve contraction: indeed, paradoxical lengthening occurred in three patients. The authors suggested that the ribcage muscles were contracting more strongly. However, a representative trace obtained before extradural block revealed an increase in gastric pressure towards the end of expiration. This pressure would act to lengthen the inactive fibres of the diaphragm in expiration, which would subsequently tend to shorten when the abdominal muscles relaxed at the onset of inspiration. Thus an alternative explanation for the paradoxical effect of extradural anaesthesia would be abolition of the lengthening in expiration, and hence less "shortening" action during inspiration. A general criticism that can be levelled at many of these studies of postoperative patients is that they were made over only short time periods, and may not have been entirely representative. Longer recordings show frequent changes in respiratory pattern, with abnormalities developing and disappearing, sometimes quite quickly. Abnormal breathing patterns are significantly related to airway obstruction.[9]

Considering the complex interactions of the respiratory muscles, to expect that the action of the diaphragm could be analysed and assessed with a single simple measurement was unrealistic. The uncritical application of the concepts of abdominal and pleural pressure change associated with diaphragm action, in clinical circumstances where the other respiratory muscles are acting, often powerfully, has stimulated a lot of research, and a cloud of misconception. Now, with more careful study, the clouds are clearing, but the view is far from simple. Clearly, the abdominal muscles have an important role in the breathing pattern of the patient after abdominal surgery. It is not evident if the abnormalities in breathing, of themselves, require treatment, or how they could be altered if this were desirable. These changes in respiratory mechanics could conceivably be an appropriate and effective response to surgical trauma.[7] However, lung collapse and infection remain difficult problems for patients after abdominal surgery, and abnormalities in abdominal muscle activity may contribute to them: careful clinical physiological measurements and clear thinking are needed to tease out the links and develop effective therapies.

EDITORIAL II

Animal tissues into humans

Because of concerns regarding the increased likelihood of organs from genetically modified animals soon being transplanted into humans in the UK, the Secretary of State for Health has established a group under the chairmanship of Professor Ian Kennedy. Its terms of reference were: "In the light of recent and potential developments in xenotransplantation to review the acceptability of and ethical framework within which xenotransplantation may be undertaken and to make recommendations". This group has now reported.[1]

Clinical procedures involving xenotransplantation demonstrate several problems associated with this technique: ethics, physiological differences, immunological rejection and infection. Heart, kidney, liver, lungs, islets of Langerhans (pancreas), neural tissue, bone marrow, skin, cornea, blood and gene therapy are of current transplant interest.

Reemtsma, McCraken and Schlegael showed in 1964 that renal transplantation from chimpanzee to humans could provide long-term function.[2] In 1994, Groth and colleagues reported the survival of porcine pancreatic endocrine tissue in 10 diabetic patients.[3] A baboon-to-human bone marrow transplant in a patient with AIDS was reported in the USA in 1996 but failed to engraft.[4] Starzl and co-workers from Pittsburgh reported a baboon-to-human liver transplant which survived without significant rejection for 70 days in a patient with HIV and hepatitis B virus associated with chronic active hepatitis.[5] In the USA one research group has received approval from the Food and Drug Administration (FDA) to use livers from genetically modified pigs as *ex vivo* support for patients with liver failure waiting for human organs to become available. In the UK, at least one company is developing genetically modified pigs for use as source animals for xenotransplantation. In September 1995, one UK company announced the results of research involving the heterotopic transplant of pigs' hearts into cynomologous monkeys.[1] They have indicated that it is their intention to move to xenotransplants involving humans over the next 12 months. The Nuffield Council on Bioethics has recently given its approval in a report on xenotransplantation for pig organs to be transplanted into humans.[6] The council also called for a statutory advisory committee to be in place before the first xenotransplants are carried out in humans.

Possible harms surrounding xenotransplantation that were identified by the group include:

(1) effects on the animal of genetic modification and effects on the human of transplantation;
(2) possible excess suffering of patients when the transplanted tissue does not function or the possible harm to future humans by the introduction of new virus strains;
(3) possible suffering of the animals involved;
(4) diversion of research away from techniques which may eventually improve the shortfall in human tissue availability;
(5) diversion of funds from other areas of health care.

Not all animals are an appropriate source of organs and tissue for transplantation into humans. The appropriateness of the choice of animal depends on several factors. The anatomical, physiological and genetic characteristics of the animal are crucial. The animal species chosen must be easily bred in large numbers, possibly in special pathogen-free environments. There is a real risk of the animal acting as a vector for transmission of infection to humans. In addition, there is the ethical acceptability of using a particular animal for the purpose of producing organs for transplantation to humans.

Clearly, there are also different cultural and religious backgrounds and beliefs which make the use of either some or no animals suitable for xenotransplantation. This is either because of ethical objections to the use of animals in this way, or the unacceptableness of the transplant procedure itself. Is it ethically justifiable? Religious and secular thinking in the West have tended in the past to give animals a low status. It is argued that humans have the capacity for autonomous action and are on that account "ends in themselves". Animals do not have this capacity and so their value is simply to be a means to human ends. However, there has been much recent popular interest in the rights of animals–the "green movement", the "animal rights movement" and the trends to vegetarianism and "not tested on animals" policies seen with some products.

The group's view was that animals do have rights and while there is no fundamental right not to be used for xenotransplantation, animals should not be so used in circumstances which violate unjustifiably the minimum rights they may have. Their interests must be considered in any assessment of the benefits and harms arising from the introduction of xenotransplantation. The group considered that animals vary a great deal in their complexity and presumably in their capacity for suffering. Primates are at the higher end of this scale, and have close affinities with humans, in particular their mental capacity, self-awareness and capacity for suffering. They consequently argued that it would be ethically unacceptable to use primates as source animals for xenotransplantation. The arguments that ruled out primates did not however, rule out the pig. The balance of potential benefits to humans *vs* the harm involved to the pig was such that the group felt it acceptable to use the pig for xenotransplantation.

Not all xenotransplantation procedures involve genetic modification of animals. However, all other aspects being met, what are the limits of acceptable genetic modification? Does such modification change the entity from what it was, and does it harm the animal? The group considered that there should be concomitant benefit to humans, and the pig should neither suffer unduly nor cease recognizably

    - *Cryptosporidium*
  - Prions

to be a pig. Constant monitoring of the animals which have been modified and assessments of the proposed genetic modifications are both required.

Ethical issues apart, infection is the next single most important aspect of xenotransplantation. Assuming that the transplant were to function correctly and not be rejected, there would always remain the possibility that an infection could be transmitted from the source animal to the recipient, or perhaps more worrying to the wider population (table 1).

Viruses pose the greatest risk of infection—both known and unknown. The group considered it unsafe to proceed with clinical studies at the current time as there is insufficient knowledge about known viruses. When such data are available they suggest that a system should be in place to monitor the emergence of any unusual disease or any unknown pathogens and to require, as a consequence, that appropriate additional research be completed.

The group's major recommendation was the establishment of a National Standing Committee backed by legislation. This committee would have overall national responsibility for overseeing the development of xenotransplantation; that is the transplant of viable, replicating animal tissue into humans. It would set standards and ensure their implementation. The committee would co-ordinate its activities with those of the local research and ethics committees (LREC) and any proposal for research into xenotransplantation involving humans would be approved by the National Standing Committee before approval by a correctly constituted LREC. The power of the National Standing Committee would be exercised through the local research and ethics committees.

There is already in place legislation covering some aspects of the recommendations, namely the Animals (Scientific Procedures) Act 1986. This in particular covers the types of animal used and the extent of harm or suffering considered acceptable, in addition to the detailed manner in which such animals are bred and housed. The Government was, however, in broad agreement with the recommendations of the group and has established the UK Xenotransplantation Interim Regulatory Authority (UKXIRA) to be chaired by Lord Habgood. The Secretary of State has welcomed views and has initiated a wider consultation of the proposals.

CLINICAL INVESTIGATIONS

Pulmonary function and pain after gastroplasty performed via laparotomy or laparoscopy in morbidly obese patients†

J. L. JORIS, V. L. HINQUE, P. E. LAURENT, C. J. DESAIVE AND M. L. LAMY

Summary

We have compared severely obese patients (body mass index >35 kg m^{-2}) undergoing laparoscopic or open gastroplasty ($n = 15$ in each group) to determine if laparoscopy results in any benefit in the obese. Postoperative pain, measured on a 100-mm visual analogue scale, and opioid consumption were recorded during the first two days after operation. Tests of pulmonary function were performed and Sp_{O_2} was measured 4 h after surgery and on days 1, 2 and 3 after operation. Pain at rest was similar in the two groups, but in the laparoscopy group, requirements for postoperative opioid were 50% less ($P < 0.05$). Pain intensity during mobilization and on coughing was significantly less after laparoscopy (differences between mean pain scores in both groups ranged from 20 to 32 mm during mobilization and from 32 to 34 mm during coughing). Forced vital capacity, forced expiratory volume in 1 s and peak expiratory flow rate were reduced significantly less after laparoscopic gastroplasty than after open gastroplasty (on day 1 forced vital capacity was reduced by 50% compared with 64%, forced expiratory volume in 1 s was reduced by 50% compared with 66% and peak expiratory flow rate by 45% compared with 60%). Sp_{O_2} values were significantly greater in the laparoscopy group (day 1: mean 95 (SD 2) % *vs* 91 (5) %; day 3: 97 (1) % *vs* 94 (3) %). This study suggests that the beneficial effects observed after laparoscopic gastroplasty in morbidly obese patients were similar to those reported after laparoscopic cholecystectomy in non-obese patients. (*Br. J. Anaesth.* 1998; **80**: 283–288)

Keywords: lung, function; complications, obesity; pain, postoperative; surgery, laparoscopy; surgery, laparotomy

Obesity results in multiple pathophysiological disturbances, including cardiovascular, respiratory, gastrointestinal, metabolic and pharmacological changes. These changes complicate perioperative anaesthetic and surgical management of obese patients. Consequently, postoperative morbidity and mortality are higher in obese than in non-obese patients.[1 2] Obesity significantly increases the risk of postoperative hypoxaemia and pulmonary complications, particularly after upper abdominal surgery.[3 4] These observations are clinically relevant as up to 23% of the population in Europe and 33% in the USA is obese, and almost 5% of the USA population weigh more than twice their ideal body weight.[5 6] Furthermore, morbidly obese patients are frequently scheduled for abdominal surgery, such as gastroplasty, to treat diet-resistant obesity.

Laparoscopic cholecystectomy results in less postoperative pulmonary dysfunction,[7–12] faster recovery of preoperative pulmonary function[10] and less atelectasis[9 10] than open laparotomy. Postoperative pain or opioid requirements, or both, are also reduced after laparoscopy.[7 8 11–13] All of these postoperative benefits facilitate early chest physiotherapy, mobilization and ambulation, which may be particularly beneficial for obese patients.[2] Laparoscopic cholecystectomy, initially considered to be contraindicated in obese patients for technical reasons, is now performed regularly in these patients and is associated with similar postoperative clinical benefits to those reported in non-obese patients. These include earlier resumption of diet, reduced duration of hospitalization and fewer complications compared with laparotomy.[14–18] Nevertheless, the benefits of laparoscopy on postoperative pulmonary dysfunction may be less in obese patients. Indeed, we observed that pulmonary function tests in morbidly obese patients after open gastroplasty[19] were affected to a greater degree than in non-obese patients after open cholecystectomy.[7–12] Similarly, Johnson and colleagues reported that improvement in postoperative pulmonary restrictive syndrome observed after laparoscopy might be less in obese than in non-obese patients.[9] However, they included only eight moderately obese patients. To our knowledge, no studies have explored the pathophysiological changes after laparoscopy in morbidly obese patients.

The laparoscopic approach has now been extended to gastroplasty.[20] Therefore, we compared prospectively postoperative pain and pulmonary function after gastroplasty performed via laparoscopy or laparotomy in severely and morbidly obese patients, to determine the potential benefits of the laparoscopic approach compared with the open procedure.

Patients and methods

The study was conducted after obtaining approval from our institution's Ethics Committee and informed consent from all patients. We studied 15 consecutive patients undergoing elective laparoscopic gastroplasty and 15 undergoing open gastroplasty. These patients had suffered severe obesity (body mass index (BMI) greater than 35 kg m^{-2}) for more than 5 yr and were resistant to dietary treatment under medical control. None of these patients had cardiac or intrinsic pulmonary disease.

We used the same anaesthetic technique in all patients. Anaesthesia was induced with clonidine 0.3 mg i.v. given over 10 min, propofol 2 mg kg^{-1} i.v. and sufentanil 20 µg i.v. Orotracheal intubation was facilitated by succinylcholine 1 mg kg^{-1}. General anaesthesia was maintained with isoflurane and 50% nitrous oxide in oxygen. Intraoperative neuromuscular block was produced with atracurium. At the end of surgery, residual neuromuscular block was antagonized with neostigmine 2.5 mg and atropine 1 mg.

Open gastroplasty consisted of reduction of the stomach with creation of a small pouch using four vertical rows of staples associated with a silastic ring, as described by Laws.[21] Gastric resection was not performed. Gastroplasty was performed via a midline incision extending from the xiphoid notch to the umbilicus. In the laparoscopy group, an adjustable silicone gastric band (Inamed, Breda, The Netherlands) was used to create a small upper gastric pouch of 15 ml in volume.[20] The surgical approach (laparotomy *vs* laparoscopy) was determined by the patient's acceptance of the laparoscopic technique and agreement by the patient to pay for the silicone band used for laparoscopic gastroplasty. It should be noted that in Belgium, laparoscopic gastroplasty costs patients three times more than laparotomy. No patient in either group had a nasogastric tube after operation.

POSTOPERATIVE ANALGESIA

All patients received the same postoperative analgesic therapy: i.v. patient-controlled analgesia (PCA) with piritramide, a synthetic opioid (Dipidolor, Janssen Pharmaceutica, Beerse, Belgium) combined with i.v. administration of propacetamol, a precursor of paracetamol, 2 g every 6 h (Prodafalgan; UPSA Medica, Brussels, Belgium: propacetamol 2 g = paracetamol 1 g). PCA settings were: bolus dose = piritramide 1 mg, lockout interval = 5 min, maximum dose = 20 mg every 4 h; no continuous infusion was used. Patients were instructed before operation in the use of the PCA pump. Pain scores were recorded on a 100-mm visual analogue scale at rest, during mobilization (patients were asked to move from the supine to the sitting position) and on coughing. Pain intensity was measured 4 h after surgery, at 08:00, 13:00 and 18:00 on day 1, and at 08:00 on day 2 after operation. Postoperative piritramide consumption was measured every 4 h until 40 h after operation.

PULMONARY FUNCTION

Pulmonary function testing was performed in the sitting position by the same technician who was blinded to the patient allocation group, on the day before surgery, 4 h after surgery and on days 1, 2 and 3 after operation. The following variables were recorded: forced vital capacity (FVC), forced expiratory volume in 1 s (FEV$_1$) and peak expiratory flow rate (PEFR). These variables were measured using a Microlab 3000 series bedside spirometer (Micro Medical Ltd, Rochester, England). Capillary haemoglobin oxygen saturation Sp_{O_2} was also measured using a Datex Cardiocap pulse oximeter (Datex, Helsinki, Finland) after breathing room air for 15 min. Patients in both groups had the same regimen of chest physiotherapy combined with incentive spirometry after operation.

Table 1 Patient data, duration of surgery (mean (SD or range) or number) and duration of hospital stay (median [range]) in patients undergoing laparoscopic or open (laparotomy) gastroplasty. *P<0.05 compared with laparotomy group

	Laparoscopy group	Laparotomy group
Age (yr) (mean (range))	33 (23–44)	32 (19–52)
Weight (kg)	113 (14)	109 (14)
Height (cm)	166 (6)	163 (7)
Body mass index (kg m^{-2})	41.2 (5.2)	40.9 (4.2)
Sex (F/M)	14/1	13/2
Duration of surgery (min)	137 (39)*	83 (30)
Smoker (Y/N)	10/5	7/8
Postop. hospital stay (days)	4 [4–5]	4 [4–6]

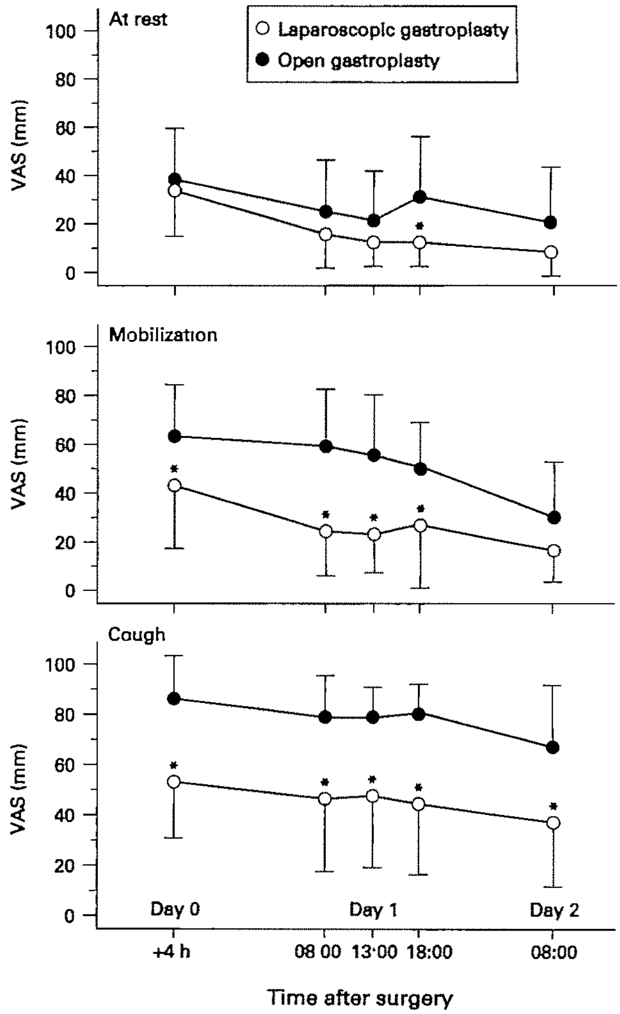

Figure 1 Pain intensity (mean (SD)) at rest, during mobilization and on coughing after laparoscopic or open gastroplasty. Pain was measured using a 100-mm visual analogue scale (VAS). *P <0.05 compared with the laparotomy group.

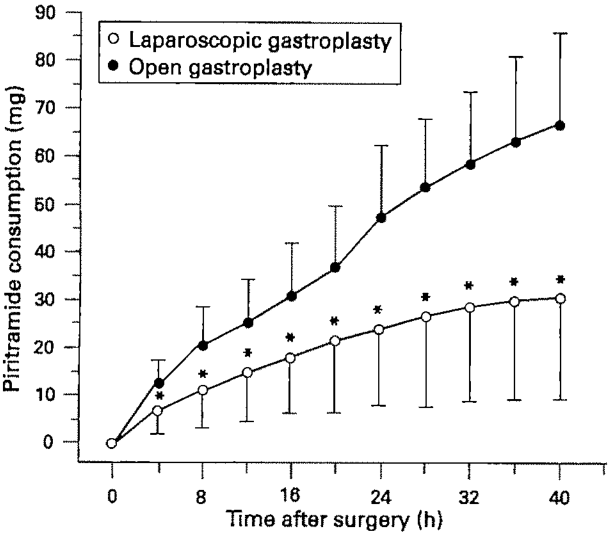

Figure 2 Cumulative postoperative piritramide consumption (mean (SD)) recorded from a patient-controlled analgesia pump after laparoscopic or open gastroplasty. $^*P < 0.05$ compared with the laparotomy group.

STATISTICAL ANALYSIS

Results are reported as mean (SD). Data were analysed by two-way analysis of variance followed by Scheffé's test. Patient data were compared using the unpaired Student's *t* test or the Mann–Whitney test, where appropriate. Results were considered statistically significant at the 5% critical level.

Results

Patient characteristics and duration of hospital stay were similar in the two groups. Nine patients in the laparoscopy group and 11 patients in the laparotomy group had a BMI greater than 40 kg m^{-2}. Duration of surgery was significantly longer in the laparoscopy than in the laparotomy group (table 1).

Pain intensity at rest, during mobilization and on coughing decreased significantly over time in both groups after surgery. Pain scores at rest were similar in the two groups, except at 18:00 on day 1 when patients in the laparotomy group reported significantly more pain than those in the laparoscopy group. Pain during mobilization and on coughing was significantly more intense in the laparotomy group throughout the study (fig. 1). Opioid consumption was significantly reduced in the laparoscopy group as early as 4 h after surgery (fig. 2). Interestingly, whereas opioid consumption decreased significantly over time after laparoscopy, a significant increase in opioid consumption was observed in the laparotomy group 20 h after surgery, which corresponded to the morning of the first day after operation.

FVC, FEV_1 and PEFR decreased significantly in the two groups after operation. However, FVC, FEV_1 and PEFR were significantly higher in the laparoscopy group than in the laparotomy group at each time after surgery. Furthermore, the rate of recovery towards preoperative values for these three variables was significantly faster in the laparoscopy group, particularly for FEV_1 and PEFR (fig. 3). Sp_{O_2} values were significantly decreased in both groups 4 h after surgery and on the first day after operation. However, the laparoscopy group had a significantly higher mean Sp_{O_2} on the first and third days after operation (fig. 4).

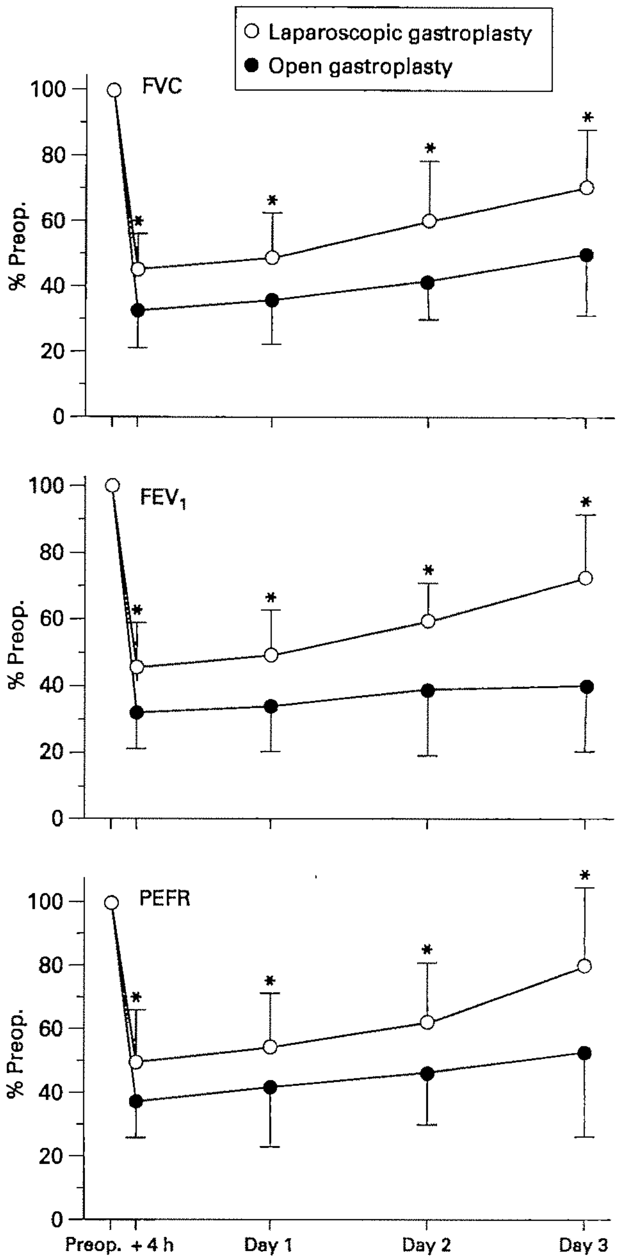

Figure 3 Forced vital capacity (FVC), forced expiratory volume in 1 s (FEV_1) and peak expiratory flow rate (PEFR) after laparoscopic or open gastroplasty. Data (mean (SD)) are expressed as percentage of preoperative values. $^*P < 0.05$ compared with the laparotomy group. The rates of recovery of FVC, FEV_1 and PEFR were steeper in the laparoscopy than in the laparotomy group.

Discussion

This study has demonstrated that laparoscopic gastroplasty resulted in less postoperative pain, reduced opioid consumption and less postoperative pulmonary dysfunction compared with open gastroplasty. These findings suggest that severely (BMI 35–40 kg m^{-2}) and morbidly (BMI 40–50 kg m^{-2}) obese patients benefit from similar advantages after laparoscopy to those observed in non-obese patients.

Pain at rest did not differ between the two groups except at 18:00 on the first day after operation. Indeed, as patients in both groups were provided with PCA, they could titrate opioid administration to

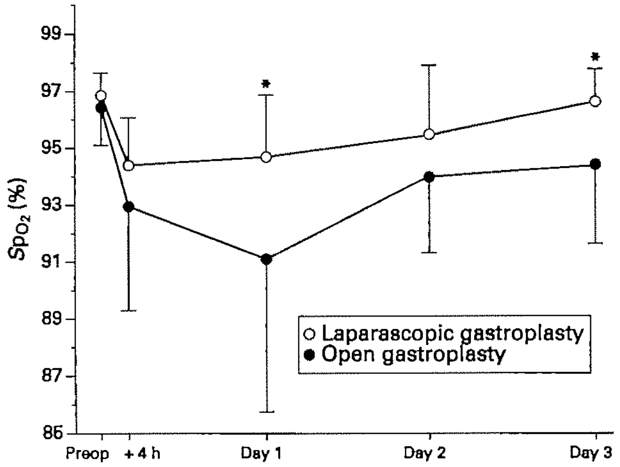

Figure 4 Capillary haemoglobin oxygen saturation Sp_{O_2} (mean (SD)) after laparoscopic or open gastroplasty. $*P < 0.05$ compared with the laparotomy group.

obtain similar levels of presumably satisfactory analgesia at rest. However, opioid requirements to reach this level of analgesia were significantly less after laparoscopy. After laparotomy, continual stimulation of the abdominal wall incision results in persistent pain and consequently greater opioid consumption. Patients, although in bed for the first 20 h after operation, were more mobile and active on day 1, leading to increased nociception. Accordingly, an increase in opioid consumption was observed in the laparotomy group 20 h after operation. Conversely, laparoscopy does not involve a large surgical incision and spares the abdominal wall the trauma of surgical retractors. Consequently, parietal pain is reduced after laparoscopy and is also more short-lived.[22] Moreover, movement, coughing and ambulation result in less pain, and opioid consumption continues to decrease on day 1. The reduction in opioid consumption observed after laparoscopy is particularly useful in obese patients who are thought to be more sensitive to the side effects of opioid analgesia than non-obese patients.[1]

The pathogenesis of postoperative pulmonary restrictive syndrome seen after laparotomy includes several factors, such as the site and size of incision,[23 24] postoperative pain[23 25] and diaphragmatic dysfunction.[26–28] Abdominal wall trauma and postoperative pain are reduced significantly after laparoscopy.[7 8 11 13] Moreover, diaphragmatic impairment is also less after laparoscopy than after laparotomy.[29–31] Consequently, laparoscopy results in less postoperative pulmonary dysfunction.[7–12] Our study showed that the reduction in pulmonary dysfunction reported after laparoscopy in non-obese patients is also present in severely and morbidly obese patients. This effect was observed despite longer surgical times in the laparoscopy group. Furthermore, the slopes of the recovery curves for FVC, FEV_1 and PEFR were steeper in the laparoscopy group than in the laparotomy group. The faster recovery to preoperative values may result from differences in pain characteristics after these two surgical approaches. Parietal pain, which affects effort-dependent spirometric volumes is not only less intense, but more short-lived after laparoscopy than laparotomy.[7 22] Similarly, duration of diaphragmatic dysfunction also seems to be shorter after laparoscopy.[30 31] Moreover, the reduction in pain and opioid consumption observed after laparoscopy may facilitate chest physiotherapy, early mobilization and ambulation, all of which help to prevent the development of postoperative atelectasis and secondary hypoxaemia.[32–34]

This study has confirmed that pulmonary function tests after open upper abdominal surgery were affected to a greater degree in obese[19] than in non-obese patients.[7–12] Similarly, the decrease in pulmonary volumes measured after laparoscopy in our obese patients were greater than those reported in non-obese counterparts.[7–12] Several mechanisms may contribute to the more severe postoperative pulmonary restrictive syndrome observed in obese patients. Obesity is associated with reduced functional residual capacity.[35] The magnitude of the decrease in functional residual capacity required for spontaneous ventilation to decrease within the closing volume is, therefore, less in obese than in non-obese patients.[4 36] As a consequence, the postoperative decrease in lung volumes is more likely to result in gas trapping, atelectasis and hypoxaemia. Even small postoperative changes may produce more significant effects in these patients. Diaphragmatic dysfunction is one of the main determinants of the postoperative restrictive syndrome.[26 27] Because of reduced thoracopulmonary compliance in obese patients,[37] the pressure gradient generated by impaired diaphragmatic contraction (even if similar in obese and non-obese patients) would result in mobilization of smaller lung volumes. Finally, respiratory muscle work load is increased and the efficiency of breathing is decreased in obese patients.[38] Postoperative fatigue would further aggravate these pathophysiological changes and impair muscle performance.[39] Lung volumes measured by spirometry would be reduced in obese compared with non-obese patients. Nevertheless, the rate of improvement in pulmonary function observed after laparoscopy (relative to that seen after laparotomy) in the morbidly obese patient is clinically significant, as Sp_{O_2} values were significantly higher after laparoscopy than after laparotomy. Our study was not designed to reveal any benefit of laparoscopy on the incidence of postoperative pulmonary complications in morbidly obese patients. Therefore, we did not perform postoperative chest x-ray. This important clinical issue deserves to be investigated.

We do not believe that the benefits observed in the laparoscopy group resulted from differences in socio-economic class or from different levels of patient motivation between the two groups. Indeed, approximately 80–90% of the obese patients from both groups belonged to the lower socio-economic classes, as has been reported previously.[5] Although the cost difference between the two surgical approaches did not allow us to perform a randomized study, agreement to pay for the silicone band was not the primary indication for selection of surgical technique. This study was conducted soon after the development of laparoscopic gastroplasty, while the open procedure was still more popular and performed more frequently than laparoscopic surgery. Many obese patients were persuaded to choose open gastroplasty by relatives who successfully underwent this procedure, or after information received from various associations of morbidly obese patients.

Several dietary treatments had already failed in these patients, who had suffered severe obesity for more than 5 yr. For all of these reasons, motivation was high in each patient, and was similar in the two groups.

This study was carried out 6 months after the introduction of laparoscopy for gastroplasty in our institution. The surgical team was therefore still learning this laparoscopic procedure. With experience, a reduction in duration of surgery and surgical trauma can be expected. Consequently, the magnitude of the benefits observed after laparoscopic gastroplasty on postoperative pain and pulmonary dysfunction may be increased further. Because hospital stay after gastroplasty is standardized and dependent mainly on patient adaptation to the small gastric pouch, we did not observe a significant effect of laparoscopy on this variable. Further studies are necessary to compare postoperative weight loss and the incidence of early and late surgical complications after these two surgical approaches.

In summary, severely and morbidly obese patients undergoing laparoscopic gastroplasty had significantly less postoperative pain, required less opioid and had better pulmonary function after operation compared with conventional open gastroplasty. All of these benefits are particularly welcome in these patients who are at high risk of developing postoperative pulmonary complications.

Extradural S(–)-bupivacaine: comparison with racemic RS-bupivacaine†

C. R. Cox, K. A. Faccenda, C. Gilhooly, J. Bannister, N. B. Scott and L. M. M. Morrison

Summary

Bupivacaine has a chiral centre and is currently available as a racemic mixture of its two enantiomers: R(+)-bupivacaine and S(–)-bupivacaine. Preclinical studies have demonstrated that there is enantiomer selectivity of action with the bulk of central nervous system and cardiovascular toxicity residing with the R(+) isomer. The aim of this study was to compare the clinical efficacy and safety of S(–)-bupivacaine with racemic RS-bupivacaine for extradural anaesthesia. We studied 88 patients undergoing elective lower limb surgery under lumbar extradural anaesthesia who received 15 ml of 0.5% or 0.75% S(–)-bupivacaine, or 0.5% RS-bupivacaine in a randomized, double-blind study. There was no difference in onset time, maximum spread of sensory block or intensity of motor block between the three groups. Duration of sensory block was significantly longer for 0.75% S(–)-bupivacaine. We conclude that S(–)-bupivacaine has similar local anaesthetic characteristics to RS-bupivacaine when used for extradural anaesthesia. (*Br. J. Anaesth.* 1998; **80**: 289–293)

Keywords: anaesthetics local, bupivacaine, pharmacokinetics, stereoisomers; anaesthetic techniques, extradural

The structure of bupivacaine has a chiral centre and as a result it exhibits stereoisomerism.[1] It is available commercially as a racemic mixture (50:50) of its two enantiomers, dextrobupivacaine (R(+)-bupivacaine) and levobupivacaine (S(–)-bupivacaine). The two molecules are non-superimposable mirror images of each other and while they have identical physicochemical properties they have distinct pharmacological and toxicological effects.

Albright's editorial in 1979 first drew attention to the problems of cardiotoxicity related to bupivacaine.[2] There is mounting evidence from both *in vitro* and *in vivo* studies that the greater inherent cardiotoxicity resides with R(+)-bupivacaine. However, no work has been performed to ensure that this reduction in cardiotoxicity with S(–)-bupivacaine is not at the expense of reduction in clinical potency. The aim of this controlled, randomized, double-blind study was to investigate the clinical efficacy and dose response of S(–)-bupivacaine compared with standard racemic RS-bupivacaine in patients undergoing lower limb surgery under extradural anaesthesia. Aspects of drug safety were also studied in this first clinical study investigating S(–)-bupivacaine.

Patients and methods

After obtaining local Ethics Committee approval, we studied 96 patients (ASA I–II, aged 19–80 yr) undergoing elective lower limb surgery under extradural anaesthesia, recruited from three centres (48, 32 and 16 patients, respectively). After obtaining written informed consent, patients were allocated randomly to one of three groups. Each group received 15 ml, in a double-blind manner, of 0.5% or 0.75% S(–)-bupivacaine (Chiroscience, UK) or 0.5% RS-bupivacaine (Marcain, Astra).

Preoperative screening included a 12-lead ECG, urinalysis and blood for routine haematology and clinical chemistry. These were repeated in the postoperative period. Approximately 1 h after premedication with oral temazepam 10–20 mg, the patient was transferred to the anaesthetic room, venous access was established and an infusion of Hartmann's solution (maximum 500 ml) commenced. The patient was monitored by non-invasive arterial pressure measurement, continuous ECG (lead II) and pulse oximetry. With the patient in the lateral position, the skin was infiltrated with 1% lidocaine (maximum 3 ml) at the L2–3 or L3–4 interspace. The extradural space was identified in the midline with an 18-gauge or 16-gauge Tuohy needle using loss of resistance to saline. The study drug (3 ml) was administered through the needle as a test dose. After 5 min, if there was no evidence of intravascular or intrathecal injection, the remaining 12 ml of solution were injected in an incremental manner (4-ml aliquots injected over 15 s with 60 s

Table 1 Patient characteristics (mean (SD or range) or number)

	0.5% S(–)-bupivacaine	0.75% S(–)-bupivacaine	0.5% RS-bupivacaine
n	29	30	29
Age (yr)	46 (20–75)	46 (24–76)	50 (19–80)
Sex (M/F)	10/19	8/22	13/16
Weight (kg)	72 (15)	70 (15)	75 (15)
Height (cm)	166 (10)	165 (10)	169 (11)

between each aliquot) such that total injection time was 7 min 45 s. After completion of injection (time zero), the needle was removed and the patient placed supine. Surgery was not commenced until at least 30 min after completion of extradural injection.

Upper and lower levels of analgesia were tested with a 27-gauge short-bevel dental needle, at 2 and 5 min after completion of injection and at 5-min intervals for 30 min. Thereafter sensory block was assessed at 30-min intervals until it was judged to have regressed completely. Lower limb motor block was recorded using the modified Bromage scale (0 = no paralysis, able to flex knee and ankle; 1 = unable to raise extended leg but able to flex knee; 2 = unable to flex knee but able to flex ankle; 3 = unable to move lower limb) at the intervals stated above. Methods of assessments were standardized between the three centres. Haemodynamic variables (arterial pressure and heart rate) were also recorded at the same times until complete regression of block. Episodes of hypotension (defined as greater than 30% reduction in systolic arterial pressure) were treated at the discretion of the anaesthetist according to the following procedure: methoxamine 2-mg increments if heart rate >90 beat min^{-1}, ephedrine 3-mg increments if heart rate 60–90 beat min^{-1}, atropine 0.3–0.6 mg if heart rate <60 beat min^{-1}.

Evaluation of sensory and motor block, as judged adequate for surgery, was made by the anaesthetist using a three-point scale: 0 = complete failure; 1 = unsatisfactory block (inadequate analgesia, inadequate relaxation or patients requiring a general anaesthetic because of agitation or restlessness) and 2 = satisfactory block. For statistical analysis complete failure and unsatisfactory block were considered together as failures and compared with the successes (satisfactory block).

Sedation, if requested by the patient, was provided by an infusion of propofol. Verbal contact was maintained with the patient and supplementary oxygen administered. If the block was deemed inadequate for surgery, a general anaesthetic was administered to the patient (propofol infusion supplemented with bolus doses of fentanyl 50 µg).

The results were analysed using the statistical package SAS (v6.07). The power of the study was calculated using an estimate of between-subject variability from a previous study, that is an SD associated with duration of sensory block of 60 min.[3] For a difference between groups in duration of sensory block of 45 min, the power of the study was 83%. The power was 97% if this difference was increased to 60 min. Analysis of variance and the Student's *t* test or Kruskal–Wallis non-parametric analysis of variance and *z* test were used to compare groups. To compensate for multiple comparisons a sequentially rejective Bonferroni–Holm method was used. Logistic regression was used to analyse the quality of block. All tests used a significance level of 5%.

Results

We recruited 96 patients but eight were withdrawn before administration of the study drug for the following reasons: failure to meet inclusion criteria (three patients), technical failure (two), operation cancelled (two) and withdrawal of consent (one). Therefore, 88 patients were suitable for evaluation on completion of the study. The three groups were similar, with no significant differences in mean height, weight or age (table 1).

All three solutions produced extradural block within 30 min (table 2). Segmental spread of sensory block was similar in the three groups. Mean onset times for loss of sensation to pinprick were 8 min for 0.5% S(–)-bupivacaine, 6 min for 0.75% S(–)-bupivacaine and 7 min for 0.5% RS-bupivacaine. Median maximum sensory block height was T8 in the 0.5% and 0.75% S(–)-bupivacaine groups and T7 in the 0.5% RS-bupivacaine group, and median time to reach this level was 25 min in all groups. Duration of sensory block was significantly longer in

Table 4 Overall success of block (number of patients (%)). Groups 0 and 1 were considered together as treatment failures and group 2 as treatment success. No significant difference (logistic regression, P=0.71)

	0.5% S(–)-bupivacaine	0.75% S(–)-bupivacaine	0.5% RS-bupivacaine
Satisfactory block (2)	18 (62%)	23 (77%)	22 (76%)
Unsatisfactory block (1)	8 (28%)	5 (17%)	7 (24%)
Complete failure (0)	3 (10%)	2 (7%)	0

the 0.75% S(–)-bupivacaine group (P = 0.001 on the right, P = 0.016 on the left), with a mean duration of 460 min compared with 377 min for 0.5% S(–)-bupivacaine and 345 min for 0.5% RS-bupivacaine. Analysis of individual dermatomes demonstrated the block to be of longer duration in the lower lumber and sacral dermatomes.

There was no significant difference in onset time or grade of motor block between the three groups (table 3). However, in the 0.5% S(–)-bupivacaine group, 14 of 29 patients did not develop motor block and there was a trend in the 0.75% S(–)-bupivacaine group to have a longer duration of block.

There were no significant differences between the three groups in arterial pressure (systolic, mean and diastolic) or heart rate. There was a reduction in both heart rate and arterial pressure during the first hour, with a subsequent return to baseline values. Hypotension was observed in 18 patients, evenly distributed between the three groups. All episodes responded to the treatment described.

The overall success of block and its adequacy for surgery (i.e. a score of 2) was 62% in the 0.5% S(–)-bupivacaine group, 77% in the 0.75% S(–)-bupivacaine group and 76% in the 0.5% RS-bupivacaine group (P = 0.71) (table 4). Blocks described as unsatisfactory were evenly distributed between the three groups. Three patients in the 0.5% S(–)-bupivacaine group and two in the 0.75% S(–)-bupivacaine group had complete failure of block (a technical failure with drug not in the extradural space) and required general anaesthesia.

Adverse sequelae were reported to be definitely, probably or possibly related to the study medication, with similar numbers in each group. Hypotension was the most common side effect during surgery. Six patients developed difficulty with micturition in the postoperative period. Five patients described minor neurological abnormalities (three complained of areas of hypoaesthesia which were related to surgery and two of small areas of paraesthesia) all of which resolved quickly after operation. There were no serious adverse events recorded and all patients made a complete recovery. Haematology, clinical chemistry and urinalysis repeated on the first day after operation revealed only minor abnormalities which were not thought to be related to the study medication. A 12-lead ECG was also repeated and detected minor abnormalities not present on the screening ECG in five patients. In the 0.5% S(–)-bupivacaine group, one patient had a sinus tachycardia and another a sinus bradycardia with atrial ectopics; one patient in the 0.75% S(–)-bupivacaine group showed sinus tachycardia with minor T wave inversion and in the 0.5% RS-bupivacaine group one patient developed sinus tachycardia and another minor T wave inversion.

Discussion

This study demonstrated that S(–)-bupivacaine is a suitable drug for use in extradural anaesthesia as it produced a block clinically indistinguishable from the racemate. We demonstrated a significantly longer duration of sensory block with 0.75% S(–)-bupivacaine compared with 0.5% S(–)-bupivacaine and 0.5% RS-bupivacaine. Given the increased safety margin of S(–)-bupivacaine, the 0.75% concentration may be used more commonly in clinical practice. We have also shown a trend, although not statistically significant, towards less motor block with equivalent doses of S(–)-bupivacaine compared with RS-bupivacaine.

Although bupivacaine remains one of the most popular local anaesthetic agents, caution is required because of its toxicity profile, particularly in relation to the heart. This has led to withdrawal of the 0.75% concentration in obstetric practice and its complete withdrawal for i.v. regional anaesthesia.

Until recently, it was believed that there was no difference between the isomers in relation to nerve blocking potency,[4] but in 1992, Lee-Son and colleagues in an *in vitro* study of frog sciatic nerves showed R(+)-bupivacaine to be more potent than S(–)-bupivacaine at producing both tonic and phasic block (two and three times, respectively).[5] However, *in vivo* any intrinsic difference in potency of the isomers may be modulated by stereoselectivity of effect on blood vessels. Aps and Reynolds found S(–)-bupivacaine to produce longer duration of analgesia when injected intradermally in volunteers, with a greater incidence of pallor around the injection site.[6]

With regard to systemic toxicity, the LD_{50} (in rats and mice) of R(+)-bupivacaine is 30–40% lower than that of S(–)-bupivacaine.[4] The major cause of death is cardiotoxicity, manifested as cardiovascular collapse and arrhythmias, particularly ventricular fibrillation. It is unclear if this is a direct cardiac effect of the local anaesthetic, an indirect centrally mediated effect or a combination of the two.

Bupivacaine binds to cardiac Na^+ channels in a time- and voltage-dependent manner.[7] Its slow dissociation time from the channel, that is fast-in, slow-out, produces slowing of conduction of the action potential (manifested as prolongation of the PR and QRS intervals on the ECG), predisposing to the development of re-entrant arrhythmias. This effect on Na^+ conductance can be detected indirectly by measuring *V*max (upstroke velocity of the action potential). Vanhoutte and colleagues, in a study of guineapig papillary muscle, concluded that S(–)-bupivacaine reduced *V*max much less than R(+)-bupivacaine at different rates of stimulation and resting membrane potentials.[8] Valenzuela and colleagues confirmed this stereoselective effect on Na^+ channels using guineapig ventricular myocytes and illustrated a similar stereospecificity in cloned human cardiac K^+ channels, with R(+)-bupivacaine showing greater affinity.[9] [10] It would appear therefore, that when the two isomers are compared in cardiac tissue, R(+)-bupivacaine has a greater affinity for and dissociates more slowly from ion channels than S(–)-bupivacaine, thus predisposing to an enhanced potential for arrhythmias.

Mazoit, Boico and Samii compared the pharmacodynamics of the isomers of bupivacaine with the racemate on the heart using an isolated perfused rabbit heart model.[11] When given in equal doses, they found an increase in QRS duration in all three groups, which was maximal with R(+)-bupivacaine (236 ms compared with 194 ms for the racemate and 59 ms for S(–)-bupivacaine). All hearts in the R(+)-bupivacaine and racemate groups developed severe atrioventricular (AV) block compared with only two of six in the S(–)-bupivacaine group. Ventricular fibrillation subsequently occurred in 83%, 66% and 0% of R(+)-bupivacaine, racemate and S(–)-bupivacaine treated hearts, respectively. In an attempt to further clarify the precise mechanism of AV block, Graf and colleagues, using isolated perfused guineapig hearts, showed that R(+)-bupivacaine produced significantly longer AV delay than S(–)-bupivacaine and the racemate.[12] As they were unable to exhibit any stereoselectivity at the AV node itself, they concluded that this delay was caused by a stereoselective effect on the coupling mechanism between the AV node and the surrounding conduction tissue in the atria and ventricles. There is also some evidence that part of this stereoselectivity of effect on cardiac toxicity is not solely a direct effect on the myocardium but also an indirect, centrally mediated effect. Denson, Behbehani and Gregg compared the effects of the two isomers on the cell firing rate (CFR) of the nucleus tractus solitarius in the brains of anaesthetized rats after an i.v. bolus of R(+)-bupivacaine or S(–)-bupivacaine (equal doses).[13] Both isomers reduced CFR, but the time to maximum reduction was significantly longer with S(–)-bupivacaine. In addition, all animals in the R(+)-bupivacaine group died, while 10 of 12 animals given S(–)-bupivacaine survived. Malignant ventricular arrhythmias were seen in 33% of the R(+)-bupivacaine and none of the S(–)-bupivacaine treated rats.

Although care must be taken when extrapolating results from the above studies to the clinical setting, a volunteer study by Gristwood and colleagues validated many of these findings.[14] In a double-blind, crossover study, subjects (primed with lidocaine 7 days before testing) were given an i.v. infusion of either S(–)-bupivacaine or the racemate at 10 mg min^{-1} until symptoms of CNS toxicity were reported (or to a maximum of 150 mg). Both drugs were well tolerated, with mean doses of 56.1 mg and 47.9 mg for S(–)-bupivacaine and the racemate, respectively. The use of transthoracic electrical bioimpedance allowed measurement of cardiac function and myocardial contractility which demonstrated that levobupivacaine produced a significantly smaller reduction in stroke index, ejection fraction and acceleration index than the racemate.

In summary, we have shown that S(–)-bupivacaine produced extradural anaesthesia, with a block clinically similar to racemic bupivacaine. The reduced toxicity of S(–)-bupivacaine was, therefore, not at the expense of a decrease in clinical efficacy. We conclude that S(–)-bupivacaine promises to increase the margin of safety for extradural anaesthesia.

Addition of clonidine or fentanyl to local anaesthetics prolongs the duration of surgical analgesia after single shot caudal block in children

I. CONSTANT, O. GALL, L. GOUYET, M. CHAUVIN AND I. MURAT

Summary

Caudal anaesthesia is indicated for surgical procedures lasting less than 90 min. Fentanyl and clonidine are known to prolong postoperative caudal analgesia, but there are no data on their effect on duration of surgical analgesia. We evaluated if the addition of clonidine or fentanyl to local anaesthetics prolonged the duration of surgical analgesia after single shot caudal block in children in a randomized, double-blind study. We studied 64 children, aged 6–108 months, undergoing bilateral correction of vesicoureteral reflux which was expected to last more than 90 min. Patients were allocated to one of four groups: group O received 1 ml kg^{-1} of a mixture of 0.25% bupivacaine with epinephrine and 1% lidocaine in equal parts; group F received the same mixture of local anaesthetics in addition to fentanyl 1 μg kg^{-1}; group C received the same mixture of local anaesthetics in addition to clonidine 1.5 μg kg^{-1}; and group C+F received the same mixture of local anaesthetics in addition to fentanyl 0.5 μg kg^{-1} and clonidine 0.75 μg kg^{-1}. Single shot caudal block was sufficient in only 57% of children in group O compared with 93% in groups C and F and 86% in group C+F (P = 0.035). Global assessment of anaesthesia, defined as the time from caudal injection to the first administration of analgesic (either during or after surgery), was significantly longer in the three groups of children who received additives compared with local anaesthetics alone (P = 0.035), but there were no differences between the three additive groups. Vomiting was observed only in children who received fentanyl. Addition of clonidine or fentanyl to local anaesthetics prolonged the duration of surgical analgesia of caudal block, allowing single shot caudal anaesthesia to be recommended for surgery lasting 90–150 minutes. Clonidine had some advantages over fentanyl as it did not produce clinically significant side effects. (*Br. J. Anaesth.* 1998; **80**: 294–298)

Keywords: anaesthetic techniques, regional, caudal; anaesthetics local; analgesia, paediatric; sympathetic nervous system, clonidine; analgesics opioid, fentanyl

Caudal anaesthesia is used commonly in paediatric practice for orthopaedic and genitourinary surgical procedures. This simple technique allows rapid recovery from anaesthesia together with effective postoperative analgesia. However, the mean duration of surgical analgesia provided by local anaesthetics is limited and thus single shot caudal anaesthesia is indicated only for surgery expected to last less than 90 min.[1 2] In longer surgical procedures, insertion of an extradural catheter may be required to achieve sustained analgesia. However, placement of an extradural catheter is time-consuming and more expensive than single shot caudal block, and may be associated with various technical problems such as difficulty in insertion, vascular damage or leaks. To overcome these problems, various drugs have been added to local anaesthetic solutions to prolong the duration of caudal anaesthesia provided by a single injection. Fentanyl, a lipophilic opioid, is added frequently to local anaesthetics in children, but its beneficial effects are debated.[3 4] Side effects, such as nausea, vomiting or respiratory depression, are not uncommon. Extradural clonidine produces analgesia by a non-opioid spinal mechanism. This α_2 agonist is devoid of opioid side effects but may produce excessive sedation, hypotension and bradycardia in adults.[5] In children, addition of clonidine to local anaesthetics prolongs the duration of postoperative analgesia after inguinal hernia repair[6] and minor orthopaedic surgery.[7] However, there are no data on the effect of clonidine or fentanyl on the duration of effective surgical analgesia. Therefore, in this double-blind, randomized, prospective study, we evaluated if addition of clonidine or fentanyl to a mixture of local anaesthetics prolonged the duration of surgical analgesia, thus allowing single shot caudal analgesia to be recommended for surgery lasting more than 90 min.

Patients and methods

The study was approved by the Ethics Committee (CCPPRB, Ambroise Paré, Paris) and written parental informed consent was obtained. We studied children undergoing bilateral correction of vesicoureteral reflux, a surgical procedure expected to last more than 90 min. All were scheduled to receive general anaesthesia combined with caudal extradural block. A sensory block up to T10 is sufficient for this surgical procedure as skin incision is performed in

the subpubic space. Exclusion criteria were: contraindications to caudal anaesthesia; body weight greater than 25 kg; and ASA III or greater.

Children were premedicated 30–40 min before surgery with midazolam 0.4 mg kg^{-1} rectally or orally. Anaesthesia was induced by face mask with halothane and 60% nitrous oxide in oxygen. After placement of an i.v. cannula, the trachea was intubated without the use of a neuromuscular blocking agent and the lungs were ventilated mechanically (Servo 900 D, Siemens). Anaesthesia was maintained with isoflurane (0.6 MAC corrected for age). Caudal anaesthesia was performed in the lateral position with a 22-gauge lumbar puncture needle and one of the four different mixtures described below was administered on a weight-related basis into the caudal space.

Children were allocated randomly in one of four groups after induction of anaesthesia by opening a sealed envelope. Group O received 1 ml kg^{-1} of a mixture of equal parts of 1% lidocaine and 0.25% bupivacaine with epinephrine 1/200 000 (maximum dose 20 ml), with normal saline 0.1 ml kg^{-1} (the same volume as that required for additives in the other groups); group C received the same mixture of local anaesthetics in addition to preservative-free clonidine 1.5 μg kg^{-1}; group F received the same mixture of local anaesthetics in addition to preservative-free fentanyl 1 μg kg^{-1}; and group C+F received the same mixture of local anaesthetics in addition to clonidine 0.75 μg kg^{-1} and fentanyl 0.5 μg kg^{-1}. For each child, two different syringes were prepared by an anaesthetist not involved in the study; one contained the local anaesthetics and the second contained 0.1 ml kg^{-1} of either saline (group O) or the additives (other groups). The anaesthetist in charge of the patient and all nursing staff in the post-anaesthesia care unit (PACU) were blinded to the content of the solutions given extradurally.

Heart rate (HR) and systolic arterial pressure (SAP) were recorded before induction, after induction but before caudal anaesthesia, and then every 5 min after caudal anaesthesia. During surgery, adequate analgesia was defined by haemodynamic stability, as indicated by the absence of an increase in SAP or HR of more than 15% compared with baseline values obtained just before the surgical incision, with isoflurane concentration maintained at approximately 0.6 MAC (expired concentration <1%). An increase in HR or SAP within 15 min of skin incision indicated failure of caudal anaesthesia. If, more than 45 min after skin incision, HR or SAP increased by more than 15%, analgesia was considered inadequate and children received rescue opioid during operation (alfentanil 10 μg kg^{-1}). The need for rescue opioid was considered as the first end-point of the study and subsequent data obtained from those children were no longer considered. Fluid therapy was standardized during and after surgery. During surgery, children received lactated Ringer's solution 6 ml kg^{-1} h^{-1} with 1% dextrose, whereas 5% dextrose in 0.33 normal saline was given at a rate of 4 ml kg^{-1} h^{-1} in the PACU. The following times were recorded: time from caudal block to skin incision, time from caudal block to the end of surgery and time from discontinuing the volatile anaesthetic to tracheal extubation.

At the end of surgery, the trachea was extubated and children were admitted to the PACU. Analgesia, sedation, haemodynamic state and side effects were monitored in the recovery room until 6 h after caudal block. In children who did not receive opioids during operation, analgesia was evaluated every 30 min by CHEOPS[8] (children less than 5 yr of age) or a visual analogue scale (children older than 5 yr). Propacetamol 30 mg kg^{-1} was given i.v. when the CHEOPS score was greater than 6 or VAS was greater than 40 mm. Residual pain was reassessed 30 min later and nalbuphine 0.2 mg kg^{-1} i.v. was administered if pain scores remained unchanged. Times to administration of propacetamol and nalbuphine were recorded. The time from caudal block to the first postoperative analgesic administration (propacetamol) was the end-point for those children who did not receive alfentanil during surgery. Finally, global assessment of the duration of effective analgesia was performed by comparing the time from caudal block to administration of the first analgesic (either alfentanil during surgery or propacetamol after surgery).

Sedation was assessed every 30 min using a three-point sedation score: awake (0), drowsy (1) or asleep (2). SAP and HR were recorded every 30 min. Oximetry was monitored continuously and oxygen desaturation was defined as Sp_{O_2} <95%. The incidence of residual motor block was assessed on arrival in the recovery room. Urinary retention was not assessed, as a bladder catheter was left in place by the surgeon in all cases.

Before the study, the number of patients required in each group was determined after a power calculation according to data obtained from previous studies. It was assumed that duration of surgical analgesia with a mixture of local anaesthetics was 90 min (range 60–120 min),[1 2] and that addition of fentanyl would increase this time by 50%,[3 4] and clonidine by 100%, as demonstrated for postoperative analgesia.[6] The effects of fentanyl and clonidine were assumed to be additive.[9] According to this hypothesis, a sample size of 15 patients in each group was adequate with an alpha risk of 0.05 and a power of 0.8.

Continuous data were compared using one-way analysis of variance, followed by the Student–Newman–Keuls test (Statview, version 4.2). The chi-square test was used for nominal data. The global efficacy of the four techniques was analysed by survival curves using the Kaplan–Meier method followed by the logrank test.[10] The end-point for such analysis was the time to first administration of analgesia either during surgery or in the postoperative period. $P < 0.05$ was regarded as statistically significant. Continuous data are expressed as mean (SD).

Results

We included 64 children in the study but five children did not complete it because of failure of the caudal block (subcutaneous injection) in four patients and insufficient duration of the surgical procedure (80 min) in one patient. Data from 59 children were therefore analysed: 14 in group O, 15 in group F, 16 in group C and 14 in group C+F. Mean age, weight, time from caudal block to surgical incision, duration of surgery, duration of general

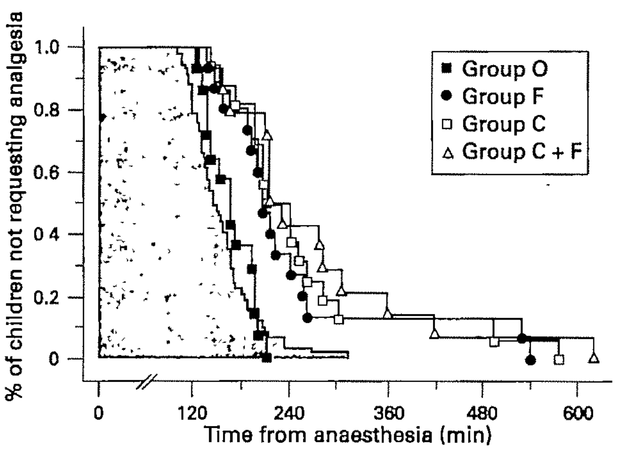

Figure 1 Effect of additives to local anaesthetics on duration of analgesia in the four groups. Time from caudal anaesthesia to first administration of analgesia either during surgery or in the postoperative period was significantly shorter in group O compared with the three other groups (logrank test = 0.035). Shaded area = actuarial curves of duration of surgery (caudal analgesia to end of surgery).

anaesthesia and time to extubation were similar in the four groups (table 1).

ANALGESIA

Surgical analgesia

Mean duration of surgery was 130 min in the four groups. Single shot caudal block provided adequate surgical analgesia in only 57% of children in group O compared with 93% in groups C and F and 86% in group C+F (chi-square test, $P = 0.035$). Six of 14 children in group O required rescue alfentanil during surgery compared with only one in group F, one in group C and two in group C+F. In patients in whom caudal block was not sufficient, alfentanil was effective in reducing SAP and HR close to baseline values.

Postoperative analgesia

Time to first postoperative analgesic administration was considered only in children who did not receive rescue alfentanil during surgery. There was a tendency for earlier analgesic requirements in group O, but this was not significant (table 2).

Global assessment

Mean duration of analgesia (defined as the time to first analgesia given either during or after operation) was significantly longer in the three groups who received additives compared with group O (245 (104) min in group F, 257 (118) min in group C, 271 (128) min in group C+F compared with 164 (30) min in group O) (ANOVA, $P = 0.035$), but no differences were observed between the three additive groups (C, F and C+F). The percentage of patients requiring analgesia as a function of time after caudal block is represented in figure 1.

HAEMODYNAMIC DATA

Baseline SAP and HR recorded before induction were similar in the four groups (table 1). Compared with baseline values, SAP decreased in all groups by 10–20% during anaesthesia, and increased by 5–20% during recovery (fig. 2). There were no significant differences in SAP profiles between the four groups. A similar decrease in HR was observed during anaesthesia in the four groups, followed by an increase during recovery. Higher values were observed during recovery in groups O and F compared with group C

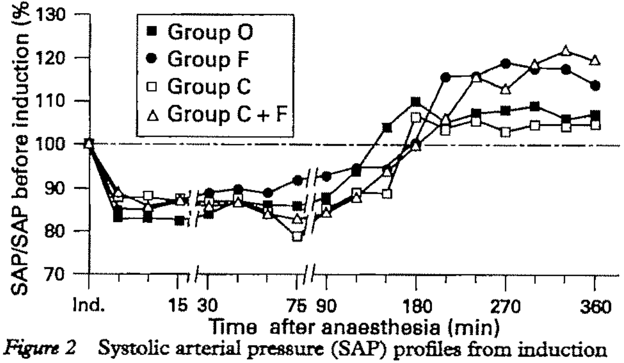

Figure 2 Systolic arterial pressure (SAP) profiles from induction (Ind.) to 6 h after caudal anaesthesia in the four groups. Changes in SAP are expressed as percentage of SAP before induction. For clarity, SD values have been omitted.

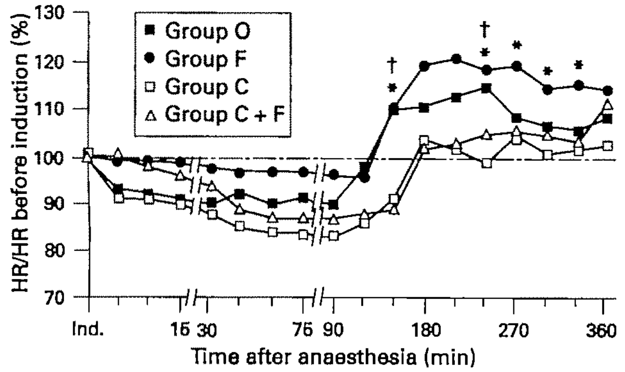

Figure 3 Heart rate (HR) profiles from induction (Ind.) to 6 h after caudal anaesthesia in the four groups. Changes in HR are expressed as percentage of HR before induction. For clarity, SD values have been omitted. $P < 0.05$: *group F *vs* group C; †group O *vs* group C.

when HR was expressed as a percentage of pre-induction values (fig. 3).

SIDE EFFECTS

Sedation scores, residual motor block on arrival in the recovery room and time to complete regression of motor block were similar in the four groups (table 3). A transient decrease in oxygen saturation to 92% was observed within the first hour of recovery in two children who received extradural fentanyl; one in a 54-month-old child in group F and the other in a 25-month-old child in group C+F. Vomiting was observed in the PACU only in children who received fentanyl (table 3). The addition of fentanyl to local anaesthetics increased significantly the incidence of vomiting compared with the two groups who did not receive fentanyl (groups O and C) (groups F and C+F *vs* groups O and C; $P = 0.011$).

Discussion

Our data demonstrated that addition of clonidine or fentanyl to a mixture of local anaesthetics prolonged analgesia provided by single shot caudal block. In paediatric anaesthesia, extradural analgesia via the caudal approach is used widely for many surgical procedures. The main disadvantage of this safe and reliable technique is short duration of action after a single injection of local anaesthetic. To avoid extradural catheter placement, and yet prolong the duration of single shot caudal anaesthesia, various additives to local anaesthetic solutions have been used.[11]

Fentanyl is added commonly to local anaesthetics administered in the extradural space to improve analgesia in the postoperative period.[12] However, few studies have addressed the benefit of fentanyl for single shot procedures. The addition of fentanyl produced only a slight change in the quality and duration of analgesia after administration of 2% lidocaine with epinephrine for a short surgical procedure[4] or after administration of 0.125% bupivacaine.[5] Therefore, it was concluded that addition of fentanyl to local anaesthetics offered no advantage over administration of local anaesthetics alone for short surgical procedures in children.

Several paediatric studies have already demonstrated that clonidine added to bupivacaine,[6 7] mepivacaine[13] or lidocaine[14] increases the duration and quality of postoperative analgesia provided by caudal anaesthesia. However, these studies were performed in children undergoing minor surgical procedures of short duration (<90 min) and there are no data on the effects of clonidine for more complex surgical procedures. Optimal extradural doses of clonidine are not well determined. In children, doses of 1 $\mu g\ kg^{-1}$ [6], 2 $\mu g\ kg^{-1}$ [7 13 15] or 3 $\mu g\ kg^{-1}$ [14] have been used without adverse respiratory or haemodynamic effects, while a decrease in SAP and HR was observed after a dose of 5 $\mu g\ kg^{-1}$.[16] In a preliminary study involving 70 children, we tested a dose of 1.5 $\mu g\ kg^{-1}$ which provided effective pain control without any clinical side effects.[17]

In our study, addition of fentanyl or clonidine was effective in increasing the duration of surgical analgesia, but we were unable to demonstrate a difference in efficacy between the three mixtures. Indeed, the SD of time to first analgesia was nearly four times greater in groups C, F and C+F than in the control group. As a result, the power achieved for the comparison of the three mixtures was extremely low (the power of this study was only 0.05 and 2000 patients would have to be included to demonstrate a significant difference between clonidine and fentanyl in terms of analgesic efficiency). One reason for such unexpectedly wide inter-individual variability may be related to the difficulties in predicting and assessing pain in the postoperative period in young children. Indeed, pain intensity and analgesic requirements may vary 5–7-fold in the postoperative period for the same surgical procedure.[18] Although all children underwent the same surgical procedure, postoperative pain remains a phenomenon that may vary greatly between individuals. Most children required supplementary analgesia in the PACU. In the clonidine group, mean time from caudal injection to first administration of an analgesic was shorter than in previous studies in which a bupivacaine–clonidine mixture was used,[6 7 15] similar to that of a mepivacaine–clonidine mixture[13] and longer than that of a lidocaine–clonidine mixture.[14]

Respiratory depression is an expected yet undesirable side effect of extradural opioids[19]; it has also been described in adults receiving extradural clonidine 300 μg.[20] In children, no respiratory depression

Table 3 Incidence of side effects. Number of patients with residual motor block on arrival in the PACU (and time to regression of motor block (mean (SD))), respiratory depression or vomiting, compared with the number of patients in each group. No significant differences

	Group O	Group F	Group C	Group C+F

Vomiting	0/14	4/15	0/16	2/14

had been reported after caudal administration of fentanyl[3,4,21] or clonidine.[6,7,14,16] In this study, two transient decreases in arterial haemoglobin saturation to 92% were observed, both in children who received extradural fentanyl.

A sedative effect had been reported after extradural clonidine in adults[20] and to a lesser extent in children.[6,7] In this study, extubation times and sedation scores did not differ in the four groups. This lack of residual sedative effect may be explained by the length of time which elapsed from caudal injection to the first sedation score (mean 3 h).

The risk of hypotension and bradycardia is an expected side effect of extradural clonidine in adults.[5] Haemodynamic effects of extradural clonidine are less pronounced in children than in adults, and may depend on the dose administered.[6,7,16] Similar arterial pressure profiles were observed in the four groups of children in this study, as reported previously after extradural bupivacaine with or without epinephrine or clonidine.[6] The increase in heart rate observed during the recovery period was less marked in the two clonidine groups compared with groups O and F. This may be because of a direct effect of clonidine or may reflect more effective analgesia.

Finally, vomiting was observed only in children who received fentanyl extradurally. The emetic effect of extradural opioid is well known and involves supraspinal mechanisms, while clonidine exhibits antiemetic properties when administered by the oral[22] or i.v.[23] route. This may be an argument for the use of clonidine rather than fentanyl as an additive to local anaesthetics when prolongation of analgesia is required.

In summary, addition of clonidine or fentanyl or a mixture of both drugs to local anaesthetics prolonged the duration of surgical analgesia after a single shot caudal injection, thus allowing single shot caudal anaesthesia to be recommended for surgery lasting 90–150 min. This could be a safe and cheap alternative to extradural catheter placement for surgical procedures of intermediate duration. Clonidine has some advantages over fentanyl, as it does not produce clinically significant side effects. Indeed, undesirable side effects such as vomiting and transient oxygen desaturation were observed only in children who received extradural fentanyl. Therefore, clonidine may be the drug of choice to prolong duration of caudal anaesthesia provided by a single injection in children.

Double-blind comparison of extradural block with three bupivacaine–ketamine mixtures in knee arthroplasty

P. S. Weir and J. P. H. Fee

Summary

We have compared 0.5% bupivacaine 75 mg (group A; *n*=15) with three 0.5% bupivacaine 75 mg–ketamine mixtures for extradural block in 59 ASA I–III patients undergoing total knee replacement in a randomized, double-blind study. The following doses of preservative-free 1% ketamine were used: 0.3 mg kg^{-1} (group B: *n*=14); 0.5 mg kg^{-1} (group C: *n*=5); and 0.67 mg kg^{-1} (group D: *n*=15). Level of sensory block, degree of motor weakness and sedation scores were recorded before and after operation. Duration of postoperative analgesia was also noted. There was no difference between groups in median maximum level of sensory block (group A: T4 (range T10–T2); group B: T4 (T10–T2); group C: T4 (T8–T2); and group D: T3 (T8–C3)) or in the degree of motor block. Thirty-three of the 44 patients who received ketamine showed signs of systemic absorption (blurred vision, sedation) within 10 min of injection. There was no significant difference between groups in median duration of analgesia (group A: 240 (range 115–340) min; group B: 198 (97–460) min; group C: 150 (122–448) min; and group D: 210 (130–390) min). No patient suffered any adverse psychomimetic effects. We conclude that at the doses used, addition of ketamine to extradural bupivacaine did not improve extradural block in adult patients undergoing total knee replacement. (*Br. J. Anaesth.* 1998; **80**: 299–301)

Keywords. analgesic techniques, extradural; anaesthetics local, bupivacaive; anaesthetics i.v., ketamine, analgesia, postoperative; surgery, orthopaedic

Total knee replacement surgery is associated with significant postoperative pain.[1] It has been suggested that continuous neural block is of particular benefit in such cases.[2] The standard postoperative analgesic regimen in our hospital after total knee replacement is extradural infusion of 0.2% bupivacaine with fentanyl 10 µg ml^{-1}. These drugs have well known side effects, bupivacaine being associated with cardiovascular instability, and fentanyl causing respiratory depression, pruritis, nausea and vomiting. Furthermore, knee replacement surgery is usually performed in elderly patients who frequently have intercurrent diseases and are already prone to complications.

Given alone, extradural ketamine has a less pronounced analgesic action than opioids.[3] However, when combined with bupivacaine it has been shown to reduce the onset time of extradural anaesthesia, increase the height of sensory block[4] and increase the duration of caudal anaesthesia in children,[5] without any of the side effects associated with opioids.[6] If these advantages are also present in adults undergoing total knee replacement, ketamine may offer the possibility of good postoperative analgesia without the use of extradural opioids, and possibly with lower total doses of bupivacaine than are currently necessary.

We have studied the effect of adding three different doses of ketamine to 0.5% bupivacaine for extradural anaesthesia and analgesia in patients undergoing knee replacement surgery.

Patients and methods

After obtaining approval from the local Ethics Committee and written, informed consent, we studied 60 ASA I–III patients, weighing 80 kg or less, undergoing total knee replacement. The use of a 100-mm visual analogue scale (VAS) for pain scores (where 0 mm=no pain and 100 mm=worst pain imaginable) was explained at the preoperative visit. All patients were premedicated with temazepam 10 mg, 2 h before anaesthesia.

An i.v. infusion of Dextran 70 in 0.9% saline 500 ml was commenced in the anaesthetic room at a rate of 500 ml h^{-1}. An extradural catheter was sited at the L3–4 or L2–3 interspace using a 16-gauge Tuohy needle and an 18-gauge multi-hole catheter. All extradurals were performed by the same anaesthetist. After a negative test dose of 0.5% bupivacaine 2 ml, patients were allocated randomly to receive one of four extradural anaesthetic regimens: group A received 0.75% bupivacaine 10 ml; group B, 0.75% bupivacaine 10 ml with ketamine 0.3 mg kg^{-1}; group C, 0.75% bupivacaine 10 ml with ketamine 0.5 mg kg^{-1}; and group D, 0.75% bupivacaine 10 ml with ketamine 0.67 mg kg^{-1}. Preservative-free ketamine 10 mg ml^{-1} (Ketalar) was used in all cases. The total volume of injectate in each group was made up to 15 ml with 0.9% saline, giving each a bupivacaine concentration of 5 mg ml^{-1}. The patient and observer were unaware of the treatment allocation.

Heart rate, arterial pressure and peripheral oxygen saturation were monitored for the duration of the study. The height of sensory block (loss of sensation to cold using ethyl chloride spray), degree

of motor block (modified Bromage scale[7]) and sedation score (using existing hospital procedure: 1=drowsy, 2=asleep but rousable, 3=unrousable) were recorded at 2, 5, 10, 15 and 20 min after extradural injection.

General anaesthesia was induced 20 min after extradural injection with propofol and maintained with isoflurane and nitrous oxide in oxygen. Patients breathed spontaneously via a laryngeal mask airway unless contraindicated, in which case they received atracurium 0.5 mg kg^{-1} to facilitate tracheal intubation and positive pressure ventilation.

After operation the same observations, together with pain scores (using the 100-mm VAS) were recorded on waking, at 120, 150 and 180 min after extradural injection, and hourly thereafter.

Hypotension (decrease in systolic blood pressure of 30% or more from the preoperative value) was treated with bolus doses of ephedrine 5 mg i.v.

As soon as patients recorded a pain score of 30 mm or greater, the time was noted, the study was deemed to be complete and rescue analgesia was given (bolus dose of 0.2% bupivacaine with fentanyl 10 μg ml^{-1} extradurally followed by continuous infusion of the same solution). The time interval from extradural injection until this point was taken as the duration of analgesia.

Table 3 Maximum height of sensory block after injection and duration of analgesia (median (range)) in the four groups (group A: 0.5% bupivacaine 75 mg; group B: 0.5% bupivacaine 75 mg with ketamine 0.3 mg kg^{-1}; group C: 0.5% bupivacaine 75 mg with ketamine 0.5 mg kg^{-1}; group D: 0.5% bupivacaine 75 mg with ketamine 0.67 mg kg^{-1}). All patients were visited 48–72 h after surgery and were questioned on the possible occurrence of dreams, hallucinations or any other psychomimetic effects of ketamine.

Data were analysed using ANOVA, chi-square and Kruskal–Wallis tests as appropriate. The study was calculated to have 80% power to detect an increase in duration of analgesia of 100%. $P<0.05$ was considered to be statistically significant.

Results

Patient characteristics are shown in table 1. One patient was withdrawn from the study because of inadvertent dural puncture.

There was no significant difference between groups in the number of patients who complained of pain on injection of the study medication, or in the number who developed hypotension within 20 min of injection. No patients became hypertensive or developed tachycardia during the study. However, compared with the control group (group A) the ketamine group had a higher incidence of sedation (table 2). In all cases, this became apparent within 10 min of injection. One patient had a sedation score of 2 (asleep but rousable), while all others scored 1 (drowsy).

There was no significant difference between groups in the rate of onset of sensory block or maximum height of block at 20 min (table 3). All patients were pain-free on waking (VAS pain score=0). When they first experienced pain, this was of sudden onset and severe, with all patients recording pain scores of greater than 30 mm. There was no significant difference in median duration of analgesia between groups (table 3). There was no difference in the degree of motor block between groups. No patient experienced hallucinations or other psychomimetic effects in the postoperative period.

Discussion

We were unable to demonstrate any increase in the rate of onset or maximum height of sensory block, or any increase in duration of analgesia resulting from the combinations of ketamine and bupivacaine. There was no significant difference in the incidence of hypotension between groups. Nine patients who were given ketamine (and one who was not) described discomfort during injection, but this was transient and not severe enough to stop the injection. The majority of patients who received ketamine reported blurred vision and drowsiness within 10 min of injection. None described this as an unpleasant sensation, and there were no postoperative sequelae.

The patients were similar in age, sex, height and weight. All had the same operative procedure, and all were cared for in the same high dependency unit after operation. There was a wide range of durations of analgesia recorded in all groups, although this does not appear to differ from other studies involving extradural anaesthesia, and probably reflects the unpredictability of spread of drugs in the extradural space. In our study, the shortest durations of analgesia were caused by regression of the block in a cephalad direction, with the upper level of the block persisting in the thoracic dermatomes.

When given extradurally or intrathecally, single boluses of preservative-free ketamine have been shown to be devoid of neurotoxic effects in animal studies.[8–11] Repeated intrathecal injections for 14 consecutive days caused no changes on light or electron microscopy of spinal cord biopsies,[12] and no neurological sequelae have been reported following the use of 1% ketamine in humans.[5]

Ketamine is a non-competitive antagonist at glutamate *N*-methyl-D-aspartate (NMDA) receptors; it inhibits the facilitated state of spinal processing caused by repetitive–persistent small afferent (C-fibre) input ("wind-up") and long-term potentiation of pain transmission.[13] Other suggested modes of action include: binding to opioid receptors[14]; local anaesthetic activity[15]; and effects on cholinergic, adrenergic and serotonergic neurotransmission.[16] It has been shown recently to potentiate the effect of extradural morphine.[17] Some authors have found that when given alone, extradural ketamine is a safe and effective drug for postoperative analgesia[18] while others have not found it to be adequate.[19] Concern has been expressed at the possibility of psychomimetic side effects, particularly when higher doses are used. These can be treated with benzodiazepines.[15] Our patients were all premedicated with temazepam. This, together with induction of general anaesthesia 20 min after injection, may have prevented these effects in our study.

Ketamine is highly lipid soluble, rapidly absorbed from the extradural space into CSF and plasma, and has a longer plasma half-life after extradural administration than if given i.v.[20] The incidence of sedation observed in our patients suggests rapid and extensive intravascular absorption of the drug from the lumbar extradural space.

Our findings do not support those of Cook and colleagues,[5] who used caudal injections for postoperative analgesia in children undergoing relatively minor surgery; their technique may result in more predictable spread of injectate. Their injections were performed after induction of general anaesthesia and so the extent of systemic absorption is uncertain; absorption of solution may be less rapid from the caudal space. In addition, Cook and colleagues used 0.25% bupivacaine; any synergistic effect of ketamine may be masked by the higher concentration (0.5%) used in our study in knee replacement surgery.

It has been shown that drug binding to NMDA receptors occurs relatively slowly,[21] and perhaps a single bolus injection provides inadequate exposure of the drug to the receptor for maximal effect. A continuous infusion may prove more effective.

We conclude that the addition of ketamine, in the doses used, to a single bolus injection of 0.5% bupivacaine had no effect on the quality or duration of extradural analgesia after knee replacement surgery.

Glycogen depletion and lactate accumulation in human intercostal muscles after administration of succinylcholine

M. Mizuno and N. H. Secher

Summary

I.m. glycogen content, lactate concentration and staining intensity for glycogen in slow- (ST) and fast-twitch (FTa and FTb) fibres were determined in the external and internal intercostal muscles after thoracotomy. Thirteen patients received a precurarizing dose of a non-depolarizing neuromuscular blocking agent followed by the depolarizing agent, succinylcholine, to facilitate intubation of the trachea (succinylcholine group). Nine patients received pancuronium or gallamine (control group). There were no significant differences in ventilatory functional capacity between the two groups. In the external intercostal muscles, lower i.m. glycogen content was observed in the succinylcholine compared with the control group ($P < 0.05$). I.m. glycogen was depleted from the FT fibres and in particular from FTb fibres, while little depletion was noted in ST fibres. In both the external and internal intercostal muscles, a higher lactate concentration was observed in the succinylcholine than in the control group ($P < 0.05$). The results indicate that the use of succinylcholine for tracheal intubation stimulated breakdown of i.m. glycogen, particularly in fast-twitch muscle fibres, and caused accumulation of lactate in intercostal muscles. (*Br. J. Anaesth.* 1998; **80**: 302–307)

Keywords: metabolism, glycogen; metabolism, lactate; muscle skeletal, metabolism; neuromuscular block, pancuronium; neuromuscular block, succinylcholine

Depolarizing or non-depolarizing neuromuscular blocking agents can be used to facilitate intubation of the trachea. After administration of a depolarizing agent, plasma potassium concentration increases.[1–3] The efflux of intracellular potassium induced by the depolarizing agent may be caused by muscle fasciculations at the onset of neuromuscular block.[4] Even after pretreatment with a non-depolarizing agent such as tubocurarine, pancuronium or gallamine, followed by succinylcholine, plasma potassium concentration is higher than after the use of a non-depolarizing agent alone.[1–3] Fasciculation of ventilatory and other skeletal muscles is observed after combined administration of a non-depolarizing and depolarizing agent.[5–7]

In a preliminary report, we noted a high lactate concentration and a low glycogen content in the intercostal muscles of surgical patients in whom the depolarizing agent, succinylcholine, was used to facilitate intubation of the trachea.[8] This occurred even though a precurarizing dose of a non-depolarizing agent was used. No control group was available, but the difference was marked compared with reported values from spontaneously breathing patients.[9] These results indicate that muscle fasciculations induced by succinylcholine cause i.m. metabolic changes similar to those observed in limb skeletal muscles during exercise. A breakdown of i.m. glycogen and accumulation of lactate occurs in proportion to the intensity and duration of exercise[10 11]; it also depends on the type of muscle fibres recruited.[12]

Human skeletal muscles,[13] including ventilatory muscles,[14] consist of two major fibre types: slow- (ST or type I) and fast-twitch (FT or type II), with FT fibre subgroups (FTa and FTb). ST fibres contract more slowly and fatigue less during repetitive contractions compared with FTb fibres.[15] ST fibres have higher mitochondrial and lower glycolytic enzyme activities than FTb fibres. Fatigue characteristics and metabolic properties of FTa fibres resemble those of ST fibres, but they contract at a speed comparable with FTb fibres.

Histochemical evaluation of muscle fibre types and estimation of i.m. glycogen in individual muscle fibres allows investigation of glycogen depletion in specific types of muscle fibres.[16–18] We have evaluated the effect of a precurarizing dose of a non-depolarizing agent followed by succinylcholine on glycogen content and lactate concentration in external and internal intercostal muscles of patients undergoing thoracotomy. Histochemical evaluation of staining intensity for i.m. glycogen in ST and FT fibres was performed and data were compared with those obtained from similar biopsies of patients who received only a non-depolarizing agent.

Patients and methods

We studied 22 patients with no history of neuromuscular disease who fasted overnight and underwent thoracotomy for benign ($n = 6$) or malignant ($n = 16$) pulmonary disease (table 1). In order to obtain data

using two non-depolarizing neuromuscular blocking agents, in four patients intubation of the trachea was facilitated by a precurarizing dose of pancuronium 1 mg, and in nine patients, gallamine 20 mg. A mean dose of succinylcholine 130 mg (range 100–150 mg) was then administered (succinylcholine group). In the other nine patients, pancuronium 8 mg ($n = 1$) or gallamine 160 mg (120–240 mg) ($n = 8$) was used for tracheal intubation (control group). Patients were allocated randomly to receive succinylcholine. The study was approved by the local Ethics Committee. In all patients, induction of anaesthesia comprised fentanyl 3 μg kg^{-1}, midazolam 0.07 mg kg^{-1} and thiopental 3 mg kg^{-1}, and was maintained with 70% nitrous oxide in oxygen. We did not use halothane or isoflurane as these agents may influence glycogen depletion and lactate accumulation in skeletal muscle after the use of succinylcholine because of "desensitization" of nicotinic cholinergic receptors.[19]

BIOPSY SAMPLING

Surgical biopsies of the external and internal intercostal muscles were obtained from the fourth to the seventh intercostal space in the mid-axillary line. The muscle sample was dissected immediately into two parts. One piece for biochemical analysis was frozen directly in liquid nitrogen. The remaining portion for histochemical analysis was mounted in an embedding medium (OCT Compound, Miels Tissue-Tek), frozen in isopentane and cooled to freezing point by liquid nitrogen. These samples were stored at −80 °C until analyses were performed. Biochemical and histochemical analyses of muscle biopsies were performed without knowledge of the drug(s) used for tracheal intubation.

BIOCHEMISTRY

The muscle samples for quantitative determination of glycogen content and lactate concentration were freeze-dried in a thermoelectric freeze-dryer (Hetosic CD 52) for 48 h at −50 °C at a pressure of 0.01 Torr. Thereafter, each muscle sample was dissected under a microscope to remove blood, fat and connective tissue in a room where the temperature (20 °C) and humidity (<30%) were controlled. The dissected fibre fragments of 1.5 (0.5–3.0) mg dry weight for glycogen and 1.3 (0.5–2.7) mg dry weight for lactate were hydrolysed with HCl 1 mol litre^{-1}. Samples for glycogen were hydrolysed further at 100 °C for 2 h; glycogen was analysed as glucose residues. Glucose and lactate concentrations were measured fluorometrically.[20] The coefficients of variance of double determinations of glycogen content and lactate concentrations were 1.8% and 5.6%, respectively.

HISTOCHEMISTRY

The frozen muscle sample was replaced in a Cryo-cut Cryostat Microtome (American Optical). In order to evaluate the relative glycogen content of individual muscle fibres, one transverse section (16 μm thick) was cut at −20 °C and stained for glycogen by the periodic acid–Schiff (PAS) reaction.[21] Under light microscopy the staining intensity of the fibres was rated as "dark", "moderate", "light" or "negative" and ranked 3 to 0, respectively.[17 18] The proportion of the four-rated intensities and mean staining intensity as an average of ranked values were determined for each muscle biopsy. The rating was performed on 392 (287–539) fibres in each muscle biopsy.

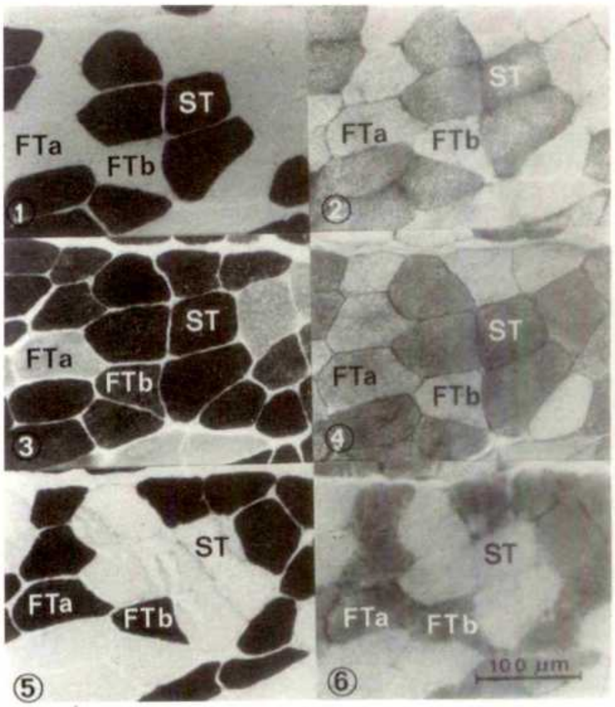

Figure 1 Photomicrographs of serial transverse sections from external intercostal muscles obtained after the use of succinylcholine. Staining for myofibrillar ATPase after preincubation at pH 4.3 (1), 4.6 (3) and 10.3 (5); for reduced nicotinamide adenine dinucleotide tetrazolium (2); for glycogen (4); and for alpha-glycerophosphate dehydrogenase (6). In the left panels (1, 3, 5) it is possible to identify ST, FTa and FTb fibres. ST fibres are stained dark in (1), whereas FTa and FTb fibres are stained dark in (5). In (3), FTa fibres are stained lighter than FTb fibres. ST and FT fibres are also identified in staining for a mitochondrial enzyme (2) and for a glycolytic enzyme (6). The level of glycogen content in individual fibres is classified in (4). The staining intensity is rated as dark for ST fibres, moderate for FTa fibres and either light or negative for FTb fibres.

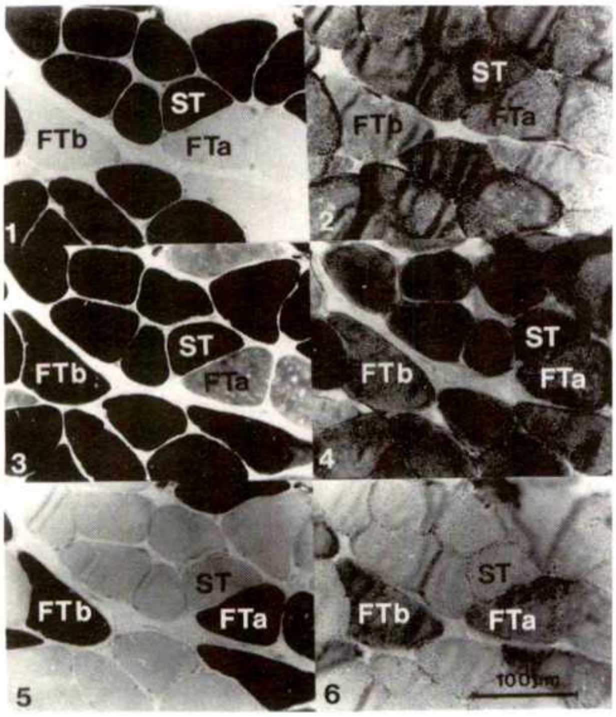

Figure 2 Photomicrographs of serial transverse sections from external intercostal muscles obtained after intubation of the trachea without the use of succinylcholine. Staining for myofibrillar ATPase after preincubation at pH 4.3 (1), 4.6 (3) and 10.3 (5); for reduced nicotinamide adenine dinucleotide tetrazolium (2); for glycogen (4); and for alpha-glycerophosphate dehydrogenase (6) (see legend to fig. 1). Note the intense glycogen staining in all three fibre types (4).

Five serial transverse sections (10 μm thick) were also cut and incubated for myofibrillar adenosine triphosphatase (ATPase) reaction at pH 9.4,[22] after preincubation at pH 4.3, 4.6 or 10.3.[23] The remaining two sections were incubated with reduced nicotinamide adenine dinucleotide tetrazolium reductase (NADH-TR)[24] or alpha-glycerophosphate dehydrogenase (α-GPD)[25] as markers for oxidative and glycolytic potentials, respectively. These sections were used to evaluate coupling between contractile and metabolic characteristics of individual fibres. Based on myofibrillar ATPase staining, individual fibres were classified under light microscopy as ST, FTa, FTb or unidentified.[26] The relative occurrence of each fibre type was determined from 544 (187–937) fibres in each biopsy. Unidentified fibres (range 0.3–1.5 %) were not included in the analysis for histochemical evaluation of i.m. glycogen.

STATISTICAL ANALYSIS

Values are expressed as mean (SD). Glycogen content, lactate concentration and glycogen staining were compared between the two groups using the Mann–Whitney *U* test.[27] Spearman's coefficient of rank correlation was use to evaluate interdependencies. A level of 5% was considered significant for two-tailed tests.

Results

There was no significant difference in patient characteristics or ventilatory functional capacity between the two groups (table 1). Mean time from the start of anaesthesia to biopsy sampling was 35 min (range 20–55 min); there was no difference between the two groups.

GLYCOGEN AND LACTATE CONCENTRATION

In the external intercostal muscle, the succinylcholine group showed a 20% lower glycogen content and a four-fold higher lactate concentration than the control group (table 1). Similarly, lactate concentration in the internal intercostal muscle was two-fold higher in the succinylcholine than in the control group, while no significant difference in i.m. glycogen content was observed. A significant correlation could not be demonstrated between lactate concentration and glycogen content or between lactate concentration determined in external or internal intercostal muscles and time of sampling of the biopsy. For both groups, comparison between external and internal intercostal muscles revealed no significant difference in glycogen content or lactate concentration. There was no difference in muscle biochemistry between patients with benign or malignant disease.

GLYCOGEN DISTRIBUTION IN MUSCLE FIBRE TYPES

The relative occurrence of ST, FTa and FTb fibres was 62 (9), 17 (9) and 21 (10) % for external intercostal muscles and 59 (18), 39 (15) and 2 (3) % for internal intercostal muscles (ns between groups).

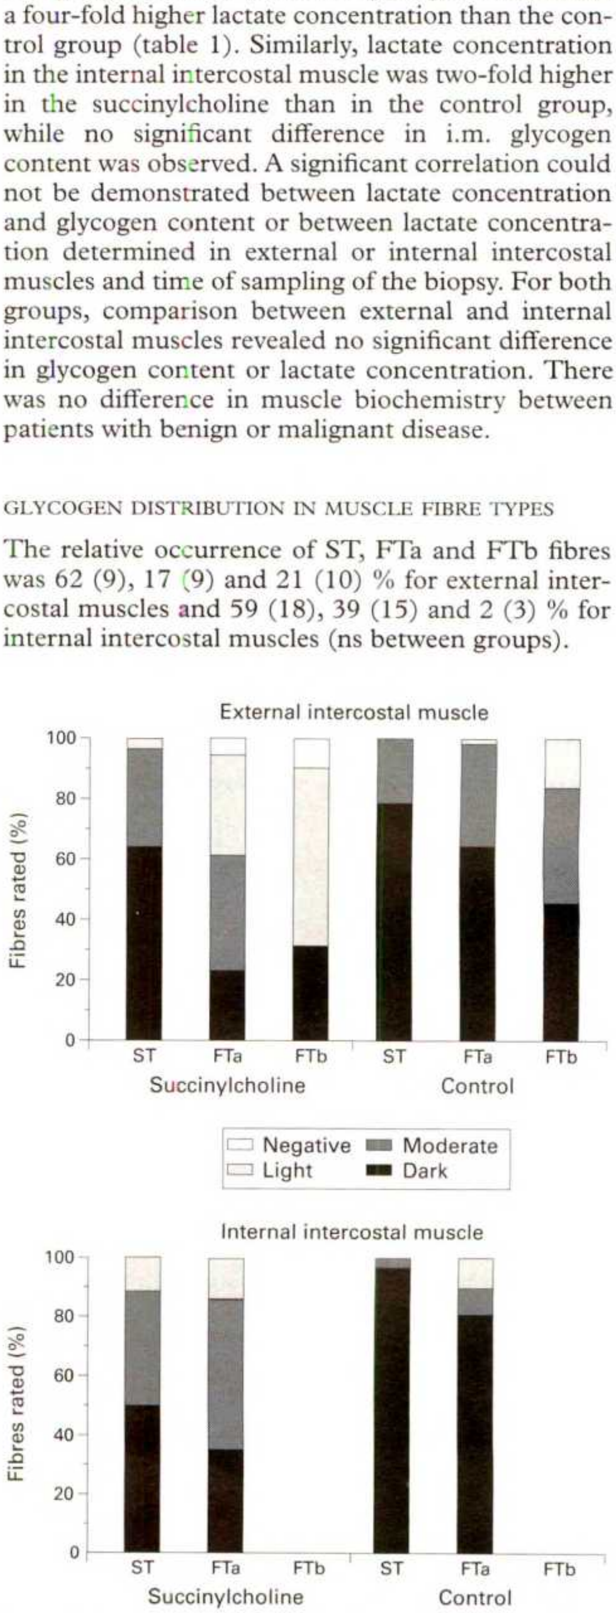

Figure 3 Glycogen depletion pattern in external and internal intercostal muscles after intubation of the trachea with (succinylcholine) or without (control) the use of succinylcholine. Y-axis shows the percentage of fibres rated. Based on the staining intensity for glycogen, individual muscle fibres are ranked as dark, moderate, light or negative ((4) in figs 1 and 2).

For external intercostal muscles, staining intensity for glycogen of ST fibres was similar in the succinylcholine and control groups (dark 65 (21) *vs* 78 (20) %; moderate 32 (14) *vs* 21 (19) %), while FTa fibres stained weaker in the succinylcholine than in the control group (dark 23 (25) *vs* 64 (28) %; moderate 38 (20) *vs* 34 (24) %; light 33 (22) *vs* 2 (7) %; negative 6 (1) *vs* 0 (0) %) (figs 1–3). In particular, FTb fibres were stained the weakest (dark 0 (0) *vs* 45 (35) %; moderate 31 (26) *vs* 38 (23) %; light 60 (23) *vs* 17 (25) %; negative 9 (13) *vs* 0 (0) %). Mean staining intensity for glycogen in FT fibres was lowest in the succinylcholine group (FTa 1.8 (0.6) *vs* 2.6 (0.3) %; FTb 1.2 (0.3) *vs* 2.3 (0.6) % ($P < 0.01$)), while a similar value was obtained for ST fibres (2.6 (0.3) *vs* 2.7 (0.3) %).

In the internal intercostal muscles, for which ST and FTa fibres were mainly identified, both fibre types were stained more weakly in the succinylcholine than in the control group (ST: dark 50 (33) *vs* 96 (8) %; moderate 39 (22) *vs* 4 (8) %; light 11 (14) *vs* 0 (0) %; FTa: dark 34 (33) *vs* 89 (23) %; moderate 52 (26) *vs* 11 (21) %; light 14 (19) *vs* 11 (21) %). Thus mean staining intensity for glycogen in both fibre types was also low in the succinylcholine group (ST 2.3 (0.5) *vs* 3.0 (0.1) %; FTa 1.9 (0.8) *vs* 2.9 (0.3) %).

ST fibres were stained darker for NADH-TR activity than FT fibres in both muscles, whereas the opposite was seen for α-GPD (figs 1 and 2). There was no difference in staining intensity for these enzyme activities between the two groups.

Discussion

We have demonstrated that the use of succinylcholine for intubation of the trachea in patients undergoing thoracotomy caused substantial breakdown of i.m. glycogen in external intercostal muscles and an increase in lactate concentration in both external and internal intercostal muscles. This was the case although a precurarizing dose of a non-depolarizing agent (either pancuronium or gallamine) was used before succinylcholine. Biochemical changes are more likely to be produced if succinylcholine alone has been administered, as the level of muscle fasciculation[5 7] and increase in plasma potassium[5] are larger without pretreatment with non-depolarizing agents. The degree of glycogen depletion in individual muscle fibres was evaluated in histochemical transverse sections stained by the PAS technique. The results indicated that i.m. glycogen in FT fibres, particularly in FTb fibres, was more depleted than in ST fibres for both external and internal intercostal muscles. The predominant effect of succinylcholine on FT fibres in this study agrees with results from human limb skeletal muscles.[28 29]

GLYCOGEN AND LACTATE CONCENTRATION

Evaluation of glycogen depletion was based on the assumption that, before operation, the level of glycogen was similar in the two groups of patients. Similar i.m. glycogen content for external and internal intercostal muscles (250 and 309 μmol g^{-1} dry weight, respectively) was reported in biopsies obtained from patients with chronic obstructive pulmonary disease during thoracotomy after administration of both depolarizing and non-depolarizing neuromuscular blocking agents.[30] In contrast, approximately half of that value (170 μmol g^{-1} dry weight) was observed in biopsies obtained from the external intercostal muscle of healthy controls under local anaesthesia during spontaneous breathing.[9] Thus glycogen content of intercostal muscles may be affected by the ventilatory capacity of the patient. It is unlikely, however, that the lower glycogen content and higher lactate concentration observed in the succinylcholine group were caused by a difference in ventilatory capacity, as FEV_1, FVC and MBC were similar in the two groups. Further, in this study, approximately 70% of subjects had malignant disease. This is in accordance with a previous observation[30] that malignant disease does not appear to affect i.m. glycogen content and lactate concentration of external and internal intercostal muscles.

In the control group, lactate concentrations in external (7 μmol g^{-1} dry weight) and internal (11 μmol g^{-1} dry weight) intercostal muscles were similar to reported values (7–12 μmol g^{-1} dry weight), while those observed in the succinylcholine group (25 μmol g^{-1} dry weight) were higher.[9] A similar value to that determined in the control group (10 μmol g^{-1} dry weight) was also reported in biopsies obtained from both external and internal intercostal muscles after the use of succinylcholine.[30] Why lactate concentration was lower in their study compared with the succinylcholine group reported here is not obvious. One explanation could be a shorter time between the use of succinylcholine and biopsy in this study (35 min) compared with a previous study, although the time was not given.[30] Alternatively, a smaller precurarizing dose of a non-depolarizing agent could have been administered in this study. Lactate concentration determined in thigh muscles 30 min after intense exercise[31 32] corresponds to that obtained in our succinylcholine group (25 μmol g^{-1} dry weight). During recovery from extremely heavy bicycling, muscle lactate concentration reaches approximately 80 μmol g^{-1} dry weight.[32]

FIBRE TYPE SPECIFICITY OF NEUROMUSCULAR BLOCKING AGENTS

A preferential effect of succinylcholine on FT fibres was indicated in this study. This finding is supported by results from animal experiments, demonstrating that the neuromuscular blocking agent decamethonium[33 34] and succinylcholine[35] have a preference for muscles dominated by FT fibres. In contrast, the non-depolarizing neuromuscular blocking agent, tubocurarine, has a preference for muscles dominated by ST fibres.[33 34] Similar findings are available from human extremity skeletal muscles with respect to the isometric mechanogram and force during maximal voluntary contraction[36 37]; endurance time[38] and electromyographic activity during a sustained contraction[28]; glycogen depletion pattern during cycling[39]; and ^{31}P-NMR detected energy metabolism during rhythmic forearm exercise.[29]

Coupling between the pattern of i.m. glycogen depletion and involvement of a specific type of muscle fibre is demonstrated during low intensity exercise with selective glycogen depletion from ST fibres, while high intensity exercise results in depletion of glycogen from FT fibres,[17 18 29] and in particular from FTb fibres.[40] However, there may not be a direct link between the pattern of i.m. glycogen depletion and involvement of specific muscle fibres during muscle fasciculations after the use of succinylcholine. Quantitative analyses of single human muscle fibres reveal that FT fibres have larger glycolytic potentials than ST fibres. In addition, a subgroup of FT fibres (FTb fibres) show the largest potentials.[41] Furthermore, FT fibres use more ATP and thereby deplete a larger amount of glycogen than ST fibres during repeated electrical stimulation-induced contractions.[42] Thus there is a metabolic bias to support the preferential effect of succinylcholine on FT and, in particular, on FTb fibres. Therefore, we conclude that after administration of succinylcholine, depletion of glycogen and accumulation of lactate take place predominately in the fast-twitch fibres of human skeletal muscles.

What would be the clinical implications of selective glycogen depletion and accumulation of lactate in intercostal muscles after the use of succinylcholine? When the glycogen concentration in exercising muscles during bicycling becomes significantly low (<80 μmol g^{-1} dry weight), it is associated with reduced performance.[17] However, the reduction in i.m. glycogen in external intercostal muscle is less, and is not therefore expected to affect ventilation. Equally, the increase in muscle lactate, approximately 30 min after the use of succinylcholine, may not influence patients by the time the operation is completed, as the level of muscle lactate would by then have returned to resting levels.[31 32] However, with the combined use of depolarizing and non-depolarizing neuromuscular blocking agents during surgery, postoperative ventilatory function may be impaired by the combined effects of persistent neuromuscular block of, in particular, ST fibres by the non-depolarizing agent and weakness caused by the development of fatigue in glycogen-depleted FT fibres by the depolarizing agent.

Augmentation of the neuromuscular blocking effects of cisatracurium during desflurane, sevoflurane, isoflurane or total i.v. anaesthesia

H. Wulf, M. Kahl and T. Ledowski

Summary

We have evaluated the enhancement of cisatracurium-induced neuromuscular block by potent inhalation anaesthetic agents, by constructing dose–effect curves for cisatracurium in 84 patients during anaesthesia with 1.5 MAC (70% nitrous oxide) desflurane, sevoflurane, isoflurane or total i.v. anaesthesia (TIVA). Acceleromyography (TOF-Guard) and train-of-four (TOF) stimulation of the ulnar nerve were used (2 Hz every 12 s). Cisatracurium was administered in increments of 15 μg kg^{-1} until depression of T1/T0 >95% was reached. ANOVA was used for statistical analysis ($\alpha = 0.05$, $\beta = 0.2$). Depression of T1/T0 during potent inhalation anaesthesia was enhanced compared with TIVA. ED_{50} and ED_{95} values of cisatracurium were 15 (SD 5) and 34 (10) μg kg^{-1} for desflurane; 15 (4) and 32 (7) μg kg^{-1} for sevoflurane; and 15 (5) and 33 (9) μg kg^{-1} for isoflurane. These were significantly lower than the values for TIVA (21 (4) and 51 (13) μg kg^{-1}) ($P < 0.01$ in each case). After equi-effective dosing, times to T1/T0 = 25% were similar in all groups (19 (7), 19 (5), 20 (5) *vs* 16 (4) min). Recovery $\text{index}_{25\text{–}75\%}$ and time to a TOF ration of 0.70 were prolonged significantly by desflurane and sevoflurane compared with TIVA (18 (5), 19 (8) *vs* 12 (4) min and 43 (11), 44 (10) *vs* 35 (5) min, respectively), whereas the difference was not significant for isoflurane (14 (6) and 41 (7) min). Keywords: neuromuscular block, cisatracurium; neuromuscular block, measurement of response; anaesthetics i.v.; anaesthetics volatile, desflurane; anaesthetics volatile, isoflurane; anaesthetics volatile, sevoflurane

The neuromuscular blocking effect of neuromuscular blocking agents may be enhanced by potent inhalation anaesthetics.[1 2] The magnitude of this effect on the dose–response curve has not been investigated for the recently introduced agent, cisatracurium. This isomer of atracurium is a non-depolarizing neuromuscular blocking agent of the benzylisoquinoline type with fewer side effects than its predecessor, atracurium. The inhalation agents, sevoflurane and desflurane, have a low blood-gas solubility, resulting in rapid uptake and elimination. Their physicochemical properties allow fast recovery thus making both agents suitable for day-case surgery. Underestimation of enhancement of neuromuscular block by potent inhalation agents could result in inadvertent prolongation of block. Therefore, the interaction of cisatracurium with desflurane and sevoflurane was compared with its neuromuscular blocking effects during anaesthesia with isoflurane or total i.v. anaesthesia (TIVA).

Patients and methods

The study was planned in accordance with the recommendations outlined in "Good clinical research practice (GCRP) in pharmacodynamic studies of neuromuscular blocking agents".[3] The time required for the first twitch (T1) to recover from 25 to 75% (recovery index) after administration of cisatracurium was mean 9.5 (SEM 1.7) min during halothane anaesthesia in children.[4] Three studies in adults during TIVA reported recovery indices (25–75% recovery of T1/T0) of 17 (SD 5), 17 (SEM 1) or 12.6 (SEM 0.6) min after a single dose of cisatracurium 100 μg kg^{-1}, while recovery time to a train-of-four (TOF) ratio of 0.7 was reported to be 66.7 (SEM 4.9) min.[4–8] If a difference of 20% in potency or recovery time is considered clinically relevant, the calculated sample size would be at least 11 (6–20) patients per group for a single comparison ($\alpha = 0.05$, $\beta = 0.2$; power 80%). As comparison of both desflurane and sevoflurane with TIVA was planned, and as some drop-outs were anticipated, a sample size of 21 patients per group was deemed appropriate.

After obtaining approval from the Ethics Committee and written informed consent, we studied 84 consecutive Caucasian male or female adults (ASA I or II) in a prospective, randomized study. Patients were undergoing minor elective extra-abdominal and extra-thoracic surgery and were free from neuromuscular and endocrine disease. Exclusion criteria were: body weight greater or less than 30% of ideal; patients younger than 18 yr or older than 65 yr; pregnancy or breast feeding; history or laboratory signs of renal (creatinine >100 μmol litre^{-1}) or hepatic (γ-GT >333 nmol·s^{-1} litre^{-1}) disease; paresis; bedridden patients; medication known to interact with non-depolarizing neuromuscular blocking agents; and allergic diathesis.

Cumulative dose–effect curves for cisatracurium were determined during anaesthesia with 1.5 MAC of desflurane (4.2 vol%), sevoflurane (1.05 vol%) or isoflurane (0.75 vol%) (adjusted for concomitant use of 70% nitrous oxide) and compared with the

Hinnerk Wulf, md, Martin Kahl, md, Thomas Ledowski, md, Department of Anaesthesiology and Intensive Care, Hospital of the Christian-Albrechts-University, Schwanenweg 21, D24105 Kiel, Germany. Accepted for publication: October 10, 1997. Correspondence to H. W.

potency determined in patients during total i.v. anaesthesia (TIVA) using propofol–fentanyl. Premedication comprised a benzodiazepine orally on the evening before surgery. Anaesthesia was induced with propofol 2–2.5 mg kg^{-1} and fentanyl 100 µg i.v. in the arm opposite to that connected to the neuromuscular monitoring equipment. Inhalation anaesthetics were administered starting with 2.5–3.0 MAC and the concentration was reduced over the next few minutes to 1.5 MAC. All groups received 70% nitrous oxide in oxygen. End-tidal $P\text{CO}_2$ was adjusted to 4.3–4.7 kPa. Body temperature and skin temperature above the monitored muscle were measured and maintained above 35 °C and 32 °C, respectively, by passive warming (wrapping of the patient and arm in a cotton blanket). The arterial pressure cuff was placed on the opposite arm. Light anaesthesia or moderate hypertension (>120% of baseline) was treated initially with fentanyl 100 µg i.v. and, if necessary, by 20% increments of the end-tidal concentration of the inhalation anaesthetic or propofol infusion rate. Hypotension (<80% of baseline) was treated initially by infusion of fluids and then by decreasing by 20% end-tidal concentration of inhalation anaesthetic or propofol infusion rate.

NEUROMUSCULAR MONITORING

The left arm was used for neuromuscular monitoring and was attached to a special arm board (Armboard TOF-Guard, Biometer Int., Odense, Denmark). Neuromuscular monitoring was performed using acceleromyography (AMG) with the piezoelectric ceramic wafer placed at the distal interphalangeal joint of the thumb (TOF-Guard, Biometer Int., Odense, Denmark). Train-of-four (TOF) stimulation of the ulnar nerve via surface stimulating electrodes placed at the wrist was used (supramaximal square wave impulses with 2 Hz, applied every 12 s, 200 µs duration). All data were stored electronically and read out into a computer program for further analysis (TOF-Guard Card Reader 1.0 for Windows, supplied by Organon Teknika, Belgium). Cisatracurium was administered when steady-state conditions were reached (stable control response of AMG for 5 min)[9] and equilibrium of inspiratory and end-tidal concentrations of potent inhalation anaesthetics had occurred, as measured by a Capnomac (Datex).[10] Cumulative increments of cisatracurium 15 µg kg^{-1} were administered repeatedly (injection time <5 s into a fast running i.v. infusion) until depression of the first twitch of at least 95% was achieved.[11] The subsequent dose was administered after at least 4 min and only if three consecutive twitches of identical amplitude were demonstrated (steady state of onset). In addition to depression of the first twitch response, the following variables of neuromuscular block were obtained: duration 25% (time after injection of the last cumulative dose until 25% recovery of T1); recovery index (time to recovery of T1 from 25% to 75%); and interval T1 (25% to a TOF ratio of 0.7). Instead of TOF 0.8 (as suggested by the GCRP guidelines[5]), TOF 0.7 was used as, following our usual clinical practice, in some patients the concentration of inhalation anaesthetic had already been reduced towards the end of operation.

In case of significant baseline shift (defined as failure of T1 to recover to 85–110% with a TOF ratio >0.8), the patient was excluded from further analysis.

CALCULATIONS AND STATISTICAL ANALYSIS

Individual dose–response curves were established by plotting the logarithm of the dose against the logit transform of depression of T1 relative to baseline (100% depression of T1 was adjusted to 99%, 0% to 1%, respectively) using linear least squares regression. After testing for deviation from parallelism, group dose–response curves were established. The ED$_{50}$ and ED$_{95}$ values of cisatracurium were calculated. Data are presented as mean (SD or range). Statistical analysis was performed by one-way ANOVA (Kruskal–Wallis test with post-test; Dunnet's multiple comparison test) using GraphPad Prism 2.0. α was set at 0.05 and β was set at 0.2 (power 80%).

Results

Patients in all groups were similar in age, weight and sex distribution (table 1). Results from six patients were excluded from further analysis (drop-outs)

Table 1 Patient characteristics (mean (SD) [range])

	Sex (M/F)	Weight (kg)	Height (cm)	Age (yr)
Desflurane	12/9	74 (13) [52–98]	174 (10) [174–192]	47 [20–64]
Isoflurane	10/9	75 (12) [54–99]	174 (9) [158–194]	46 [18–63]
Sevoflurane	17/4	76 (13) [50–100]	178 (8) [160–193]	45 [18–65]
TIVA	12/5	76 (15) [54–102]	177 (9) [162–198]	42 [20–64]

Table 2 Depression of T1/T0 after three cumulative doses of cisatracurium 15 µg kg^{-1} during desflurane, isoflurane, sevoflurane and total i.v. anaesthesia (TIVA). ED$_{50}$ and ED$_{95}$ values were calculated after logit transformation (in the 45 µg kg^{-1} column, depression was set at 100% if > 95% was already reached with cisatracurium 30 µg kg^{-1}). In nine of the 17 patients in the TIVA group, a cumulative dose of cisatracurium 60 µg kg^{-1} was given to obtain twitch depression greater than 95%. Mean effect following this dose in the TIVA group was 98 (SD 3)%. Values are mean (SD) [range]. Significant difference compared with TIVA group· * $P < 0.05$, ** $P < 0.01$

	T1/T0 (%)

Isoflurane (n=19)	20 (4) [13–27]	14 (6) [7–26]	41 (6) [33–54]
Sevoflurane (n=21)	19 (5) [12–30]	19 (8) [11–40]**	44 (10) [31–65]**
TIVA (n=17)	16 (4) [8–25]	12 (4) [6–20]	35 (6) [23–42]

because of significant baseline shift ($n = 5$) or reduction of the concentration of the inhalation anaesthetic to less than 1.2 MAC ($n = 1$). In two patients in the isoflurane group and in one in the sevoflurane group, the concentration of inhalation anaesthetic was reduced intermittently to 1.2 MAC during the study because of arterial hypotension. In one patient in each of the inhalation groups the concentration was increased to 1.8 MAC intermittently.

Cisatracurium in cumulative doses led to more pronounced depression of T1 when anaesthesia was maintained with desflurane, sevoflurane or isoflurane compared with the TIVA group (table 2) ($P < 0.01$). To obtain an end-point of T1 of less than 5%, the incremental dose of 15 μg kg^{-1} was administered 2.2 (0.5) (range 1–3), 2.2 (0.5) (2–4) or 2.4 (0.6) (2–4) times in the inhalation anaesthetic groups compared with 3.5 (0.7) (2–5) times in the TIVA group.

The calculated ED$_{50}$ (dose resulting in a 50% effect) and ED$_{95}$ were significantly lower during desflurane (15 (5) and 34 (10) μg kg^{-1}), sevoflurane (15 (4) and 32 (7) μg kg^{-1}) and isoflurane (15 (5) and 33 (9) μg kg^{-1}) anaesthesia compared with the TIVA group (21 (4) and 51 (13) μg kg^{-1}) ($P < 0.01$ in each case) (fig. 1). The dose–response curves were shifted to the left without a significant effect on the slopes compared with TIVA. The degree of potentiation (ratio of ED$_{50}$ during inhalation anaesthesia/ED$_{50}$ during TIVA) was 1.4 for all inhalation anaesthetics.

After equi-effective dosing (e.g. depression of T1/T0 >95%), there were no significant differences in duration 25% for the four groups (19 (7), 19 (5), 20 (5) *vs* 16 (4) min). For desflurane and sevoflurane compared with TIVA, recovery index$_{25-75\%}$ (18 (5), 19 (8) *vs* 12 (4) min) and a TOF ratio of 0.07 (43 (11), 44 (10) *vs* 35 (5) min) were prolonged significantly. There was no significant difference in these variables for isoflurane (14 (6) and 41 (7) min) (table 3).

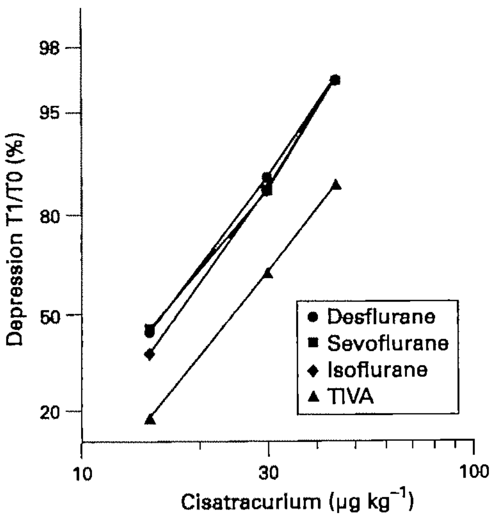

Figure 1 Log-probit plot comparing cumulative bolus dose–response curves for neuromuscular block induced by cisatracurium during desflurane, sevoflurane, isoflurane (1.5 MAC) and total i.v. anaesthesia (TIVA) (depression was set at 100% if >95% was already reached with cisatracurium 30 μg kg^{-1}).

There were no significant adverse effects attributable to the use of cisatracurium, any of the inhalation anaesthetics or TIVA in any patient.

Discussion

The aim of this study was to determine the influence of the inhalation anaesthetics, desflurane and sevoflurane, on the dose–response relationship and pharmacodynamic profile of cisatracurium. The results were compared with those obtained after total i.v. anaesthesia (TIVA). In this study the neuromuscular blocking effect of cisatracurium was enhanced by desflurane, sevoflurane and isoflurane to a similar extent.

POTENCY (AUGMENTATION OF DEPRESSION OF T1/T0)

The cumulative dose technique may underestimate the potency of neuromuscular blocking agents. However, administration of cisatracurium was standardized and the use of potent inhalation anaesthetics or TIVA was randomized; thus the cumulative pattern of cisatracurium administration would have similar effects in all groups. The aim of our study was to determine the anaesthesia-related effects of cisatracurium and not to provide absolute potency data. Nevertheless, the ED$_{95}$ obtained in the present study (51 μg kg^{-1} in the TIVA group) is in accordance with results reported by others (48 μg kg^{-1}, 53 μg kg^{-1}).[8 12]

Using a continuous infusion technique of cisatracurium, Oyos and co-workers reported (in a small number of patients; 14 in four groups) 30–40% reduction in infusion rate required to maintain approximately 95% T1/T0 suppression during enflurane–nitrous oxide and isoflurane–nitrous oxide compared with propofol–nitrous oxide or fentanyl–nitrous oxide anaesthesia.[13] Their data are similar to ours using a cumulative dosing technique during desflurane, sevoflurane and isoflurane anaesthesia. The degree of potentiation found in our study is also in accordance with that reported for other neuromuscular blocking drugs such as rocuronium (factor 1.25–1.4).[14] In theory, assuming that neuromuscular block becomes apparent at 70–75% receptor occupancy and is half maximal at 87.5% receptor occupancy, the ratio ED$_{95}$/ED$_{50}$ should be 1.95. Our results demonstrated that this holds approximately true for cisatracurium during four different anaesthetic techniques (2.26, 2.13, 2.2 and 2.4). Similar results have been obtained for rocuronium (2.06, 2.0, 1.75 and 1.92).[15]

We started our measurements approximately 10–15 min after induction of anaesthesia. Accelerometric monitoring has been shown to result in stable effects after an equilibration period of 10 min or less.[9] Inspiratory and end-tidal concentrations of each inhalation agent also indicated that steady state was approached. Diffusion of the inhaled anaesthetics into the muscle compartment is slow and requires approximately 30–45 min to approach equilibration. Recent studies indicated that a constant uptake process for desflurane and isoflurane may even continue for more than 1 h.[16] Therefore, in our study this process was probably not complete. Enhancement of neuromuscular block might still increase after more than 1 h of anaesthesia with potent inhalation agents.[17–20] Studies beyond this period are difficult to accomplish and bear little relevance to the routine clinical use of these agents.[21] Typical clinical practice is to administer the first dose of neuromuscular blocking agent soon after induction and before stable anaesthesia has been achieved. Nevertheless, because of the difference in physicochemical properties, equilibration between the muscle compartment and end-tidal concentration is faster for desflurane and sevoflurane than for isoflurane.[22 23] This phenomenon could explain the less pronounced effects of isoflurane on duration and recovery in this study.

DURATION AND RECOVERY

Duration and recovery depend on the dose of the neuromuscular blocking agent.[2 8 24] The most probable reason for the longer duration of action observed in some studies compared with our results is that cisatracurium was given in higher doses (e.g. duration 25% of 46.6 (8) min after 150 µg kg^{-1} or 68.3 (2.4) min after 200 µg kg^{-1}).[8 12] Furthermore, in our study the total dose was given in increments and therefore recovery from the first dose could have started while the last dose was being administered. This could result in underestimation of duration of action, particularly during the TIVA technique.

Mean recovery index$_{25-75\%}$ was 11.9 min in the TIVA group, in accordance with data obtained during previous investigations with barbiturate–opioid–nitrous oxide anaesthesia after a dose of 100 µg kg^{-1} (8 min[12] and 12.6 min[8]).

In summary, interaction of cisatracurium and potent inhalation anaesthetics results in potentiation of depression of T1/T0 and a leftward shift in the dose–response relationship. We used repetitive incremental dosing until 95% depression of the first twitch (end-point) was obtained in an individual patient (equi-effective dose). Using this approach of equi-effective dosing, potentiation was demonstrated in terms of ED_{50} and ED_{95} for all inhalation anaesthetics, whereas prolongation of duration of neuromuscular block was less pronounced. In contrast, if neuromuscular blocking drugs are given in identical fixed doses, regardless of the individual effective dose, differences in duration of action become more evident.

Effects of hypothermia on thrombelastography in patients undergoing cardiopulmonary bypass

S. C. KETTNER, S. A. KOZEK, J. P. GROETZNER, C. GONANO, A. SCHELLONGOWSKI, M. KUCERA AND M. ZIMPFER

Summary

Thrombelastography (TEG) correlates with postoperative chest drain output in patients undergoing cardiopulmonary bypass (CPB). *In vitro* incubation with heparinase allows TEG monitoring during CPB, despite heparin anticoagulation. Hypothermia impairs coagulation, but these effects cannot be assessed by standard coagulation tests performed at 37 °C. The aim of this study was to assess the effects of hypothermia on TEG. Therefore, we have compared normothermic and temperature-adapted TEG in 30 patients undergoing CPB. Our data showed significantly impaired reaction time (*r*), kinetic time (*k*), and angle α (α) in temperature-adapted compared with normothermic TEG. Maximum amplitude (MA), reflecting absolute clot strength, was not affected at temperatures of 33–37 °C. These findings indicate a decrease in the speed of clot formation, but not absolute deterioration in clot quality. Furthermore, heparinase-modified TEG indicated that there were nine cases in which heparin effects persisted after heparin reversal with protamine, providing a rational guide to protamine therapy. (*Br. J. Anaesth.* 1998; **80**: 313–317)

Keywords: measurement techniques, thrombelastography; heart, cardiopulmonary bypass; surgery, cardiovascular; hypothermia; blood, anticoagulants, heparin

Severe bleeding is a major complication of cardiopulmonary bypass (CPB) for open heart surgery. Various causes are known and have been investigated, for example platelet dysfunction, haemodilution, contact activation by the artificial surface of the CPB, heparin excess and inadequate heparin reversal.[1] Hypothermia induced during CPB to reduce neuronal damage may also impair coagulation. Patients undergoing hypothermic CPB show a tendency towards increased intraoperative and postoperative blood loss and an increased rate of re-operation for bleeding.[2-4]

However, the influence of hypothermia on the haemostatic system cannot be assessed by standard coagulation tests, as these tests are performed at 37 °C. Thrombelastography (TEG) is an easy and reliable coagulation monitoring system which can be performed at different temperatures.[5] In patients undergoing CPB, TEG performed at 37 °C correlates with postoperative chest tube drainage and predicts postoperative bleeding better than activated clotting time (ACT), routine coagulation screen tests or Sonoclot measurements.[6 7]

To prevent clotting in the extracorporeal oxygenator, unfractionated heparin is given before CPB, making it impossible to perform TEG with native whole blood. *In vitro* incubation with heparin-utilizing substances allows TEG monitoring during bypass, despite anticoagulation with heparin.[8]

Protamine is used for antagonism of heparin. In the absence of heparin, protamine *per se* may affect coagulation tests.[9] Thus the heparin-to-protamine ratio has to be adequate to avoid either heparin or protamine excess leading to prolongation of coagulation tests. Heparinase, an enzyme isolated from *Flavobacterium heparinum*, uses heparin without affecting coagulation tests in the absence of heparin.[10] For TEG, heparinase neutralizes high doses of heparin, enabling TEG monitoring during CPB.[8] The use of heparinase-modified, temperature-adapted TEG permits assessment of the effects of hypothermia on TEG during CPB.

Only one study has investigated the influence of hypothermia on TEG monitoring in patients undergoing liver transplantation.[11] The aetiology of coagulopathy is different during liver transplantation and open heart surgery with the use of CPB. During CPB, coagulation is affected by haemodilution and contact activation, and blood is anticoagulated to prevent clotting in the extracorporeal oxygenator. The aetiologies of hypothermia are also different. Whereas it is therapeutically indicated during CPB, hypothermia occurs accidentally during liver transplantation and can be avoided by surface warming.[12]

We have assessed the effects of hypothermia on TEG monitoring in patients undergoing CPB. We compared TEG performed at 37 °C and at body core temperature before, during and after CPB. To allow TEG during anticoagulation with heparin, we performed native and heparinase-modified measurements. Moreover, comparison of native and heparinase-modified TEG after protamine adminis-

tration may indicate the incidence of inadequate heparin reversal after CPB.

Patients and methods

After obtaining local Ethics Committee approval and informed consent, we studied 30 consecutive patients. Inclusion criteria were age >18 yr and elective primary coronary revasculation with the use of CPB under mild hypothermia. Exclusion criteria were the use of platelet altering medications within 1 week of surgery, pre-existing bleeding disorders or diabetes with severe peripheral vascular complications.

The extracorporeal circuit consisted of a membrane oxygenator with polyvinyl chloride tubing, non-occlusive roller pumps and a cardiotomy reservoir (William Harvey, USA). The oxygenator was primed with crystalloid solution 2000 ml and 20% mannitol 100 ml, containing unfractionated heparin 8000 u. and aprotinin 1 × 10^6 ku. (Trasylol, Bayer, Austria). CPB was performed with a flow rate of 2.5 litre min^{-1} m^{-2} and moderate hypothermia. Blood was cooled to 32 °C during the hypothermic phase of CPB and warmed to 37 °C during rewarming; the rate of cooling and warming was controlled to approximately 1 °C min^{-1}. We monitored blood temperature using a pulmonary artery flotation catheter, oesophageal temperature and bladder temperature. As oesophageal temperature may be influenced by cold cardioplegia solution[13] and as we wished to avoid overestimation of hypothermia, we considered bladder temperature as body core temperature. We did not use the temperature recorded with the pulmonary artery flotation catheter because of reduced lung perfusion during CPB.

Patients were given unfractionated heparin 300 u. kg^{-1} (Heparin Immuno, Immuno, Austria) before aortic cannulation to achieve an activated clotting time (ACT) of >450 s (Hemochron 800, Intern. Technidine Corp., USA). If ACT was < 450 s after administration of this initial dose, an additional bolus dose of heparin 100 u. kg^{-1} was given. ACT was monitored every 30 min until the end of CPB. If ACT was less than 400 s during CPB, additional boluses of heparin 100 u. kg^{-1} were given. The initial heparin dose necessary to achieve an ACT >450 s was neutralized after the end of CPB by protamine (Protamin Roche, Hoffmann-La Roche, Switzerland) in a ratio of 1:1.

Blood samples were obtained from an arterial cannula (or from the port of the oxygenator during CPB) before skin incision; after heparin administration; 10 min after the start of CPB; at the lowest body core temperature during CPB; immediately before protamine administration; and at the end of surgery. Samples were collected in silicone-coated glass tubes containing buffered sodium citrate 0.129 mol $litre^{-1}$ (Vacutainer, Becton Dickinson, France).

We performed four TEG measurements simultaneously on each blood sample at 37 °C and at core temperature, using native and heparinase-modified blood. Temperature-adapted measurements were not performed when body temperature was 36.5 °C or higher. TEG was performed with 300 μl of citrated whole blood and 60 μl of 0.645% $CaCl_2$. For heparinase-modified measurements, blood was incubated in heparinase vials (Hemoscope, USA) containing heparinase 4 u./ml of blood. Four commercially available temperature-adaptable Thrombelastographs D (Hemoscope, USA) were used for this investigation.

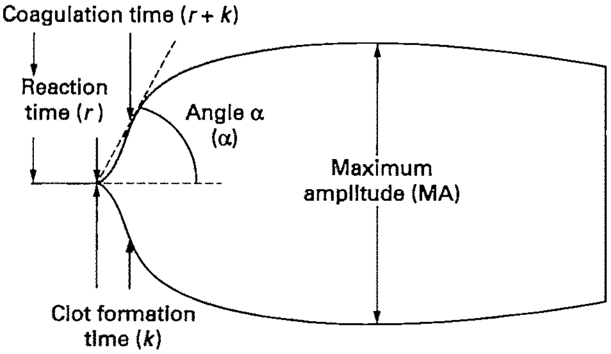

Figure 1 Normal thrombelastogram trace. Normal ranges: r = 10–19 mm, k = 4–10 mm, α = 44–55° and MA = 50–64 mm.

TEG reaction time (*r*) is the time from the start of measurement until initial fibrin formation. Clot formation time (*k*) measures the time necessary to reach 20 mm of clot strength. Coagulation time (*r+k*) is the sum of *r* and *k* (fig. 1). Values for *r*, *k* and *r+k* are expressed in millimetres (mm), as the chart speed is 2 mm min^{-1} and the time in minutes is equal to the distance in mm divided by 2 (normal ranges: *r* 10–19 mm; *k* 4–10 mm). The angle α measures the rapidity of fibrin build-up and cross-linking, which is the speed of clot strengthening (normal range 44–56°). Maximum amplitude (MA) measures maximum clot strength which is dependent on platelet function and, to a lesser extent, on fibrinogen level (normal range 50–64 mm) (fig. 1).[5]

The accuracy of temperature measurement in the TEG was verified by measuring the temperature of the thrombelastograph cuvettes filled with normal saline before the investigation. The accuracy of temperature measurement between 28 °C and 37 °C was within ± 0.2 °C. Measurements were performed with prewarmed (28 °C) disposable plastic pins and cups (Haemoscope, USA) which were inserted at least 10 min before measurement to confirm the exact temperature.

STATISTICAL ANALYSIS

After testing for normal distribution of the data, we performed ANOVA for repeated measurements to test the effects on TEG variables. The Newman–Keuls test was used to test for differences between normothermic and temperature-adapted TEG. To compare native and heparinase-modified measurements at the end of surgery, a *t* test for dependent samples was used. Statistical significance was considered at $P < 0.05$. All values are expressed as mean (SD).

Results

Thirty patients (24 males, six females; mean age 68.1 (range 40–85) yr; mean height 171.5 (SD 10.8) cm; mean weight 75.4 (12.8) kg) underwent surgery for 3.5 (0.7) aortocoronary bypass procedures. Extracorporeal circulation time was 94.6 (17.6) min, with an aortic clamping time of 52.7 (12.5) min. To achieve adequate anticoagulation, heparin 29 056 (11 880) u. were given. To reverse heparin after CPB,

protamine 26 997 (8966) u. were given (fig. 2). The course of body core temperature is shown in table 1.

Data on temperature-adapted and normothermic TEG variables, resulting from heparinase-modified measurements, are shown in figures 3–6. Body temperature reduction to 33.3 (1.6) °C during CPB prolonged r by approximately 50% and k by approximately 70% in the temperature-adapted measurements compared with the normothermic measurements. The angle α decreased by approximately 30%. MA was not affected by temperatures of 33–37 °C, but decreased significantly during surgery in normothermic and temperature-adapted measurements.

At the time of skin incision, before administration of heparin, native and heparinase-modified measurements did not differ. After administration of heparin, native TEG measurements resulted in straight lines after 60 min in all cases. At the end of surgery, after heparin reversal with protamine, native and heparinase-modified TEG were different (table 2). In nine cases heparinase-modified measurements were improved compared with native measurements (table 2). Coagulation time was the best indicator for remaining heparin effects (fig. 7).

Discussion

We have demonstrated that the heparinase-modified TEG showed significantly impaired r, k and α values in temperature-adapted measurements compared

with normothermic measurements during CPB. Similar results have been shown in hypothermic patients during liver transplantation.[11] Reaction time (*r*) represents the time necessary for building the first fibrin strands, *k* the time for reaching a certain clot strength and α represents the formation rate of the clot. Reaction time is dependent mainly on coagulation factor activity, whereas *k* and α depend on plasma coagulation and the interaction of platelets with fibrin, increasing clot stability. Impairment of these variables by temperature reduction indicates a reduction in activity of both coagulation factors and platelet function. In patients undergoing CPB, *r*, *k* and α are affected by a temperature reduction of 3.7 °C leading to an approximate 50% reduction in coagulation, as assessed by TEG. Performing ***heparinase-modified*** TEG at 37 °C in hypothermic patients may lead to underestimation of coagulopathy during CPB when hypothermia is not considered.

However, temperature-adapted TEG could lead to inappropriate therapeutic interventions if prolongation in TEG is caused by hypothermia and treated with administration of coagulation factor. Therefore, it seems appropriate to treat patients with coagulation factors or platelets only when results of normothermic TEG are abnormal. In the treatment of hypothermic patients with bleeding disorders, comparison of temperature-adapted and normothermic TEG can help to guide therapeutic interventions, for example administration of coagulation factor, transfusion of platelets, active warming or surgical re-exploration. As hypothermia impairs coagulation, it should be treated. The literature shows a decrease in blood loss in patients undergoing normothermic CPB compared with those undergoing hypothermic CPB, without an increase in adverse systemic effects.[2,4]

Maximum amplitude (MA) reflects absolute clot strength and not coagulation time, unlike *r* and *k*. Temperatures between 33 °C and 37 °C do not affect MA. This finding, together with prolonged *r*, *k* and a smaller α value, indicates a decrease in the speed of clot formation, but not absolute deterioration in clot quality, which is represented by MA. In the course of surgery MA decreased for normothermic and temperature-adapted measurements in the same manner. This indicates that TEG is able to detect impairment of platelet function caused by surgery and the extracorporeal circulation.

Two investigations showed prolongation in plasma coagulation tests caused by *in vitro* reduction of the assay temperature.[14,15] Thrombin time (TT) was less prolonged than prothrombin time (PT) and activated partial thromboplastin time (APTT). It was concluded that there may be a cumulative effect in multi-step assays, such as PT or APTT, leading to greater prolongation than in one-step assays, such as TT. Prolongation of approximately 50–60% in PT and APTT was found at 29 °C or 28 °C, respectively.[14,15] Our data showed 50–60% prolongation of TEG variables at 33.3 °C. TEG is a global assessment of haemostatic function, documenting the interaction of platelets with the protein coagulation cascade from the time of initial fibrin formation through platelet aggregation, clot strengthening and fibrin cross linkage to eventual clot lysis.[5] It is a multi-step assay of many more stages than plasma coagulation tests such as PT or APTT. The high sensitivity of TEG to temperature may be caused by cumulative slowing of the enzymatic steps of coagulation, as assessed by TEG. Alternatively, either interaction of platelets with coagulation proteins or platelet function *per se*, might be especially sensitive to the effects of hypothermia. Hypothermia-induced reversible platelet dysfunction was shown in an animal study by Valeri and colleagues.[16] In patients undergoing CPB, hypothermia reduced intraoperative platelet function and platelet recovery in the post-bypass period.[3] In that study, aprotinin reduced the negative effects of hypothermic CPB on platelet function. Although our patients received aprotinin in a much lower dose, impairment of TEG variables by temperature may be even higher when no aprotinin is given. Furthermore, aprotinin reduces clot lysis, as assessed by TEG. In fact, we found no differences in TEG clot lysis in normothermic compared with temperature-adapted measurements in our study. Only further study of the enzymatic activity of coagulation proteins and platelet activity under conditions of hypothermia will determine the extent to which different mechanisms contribute to hypothermia-induced coagulopathy.

Data in figures 3–6 are from heparinase-modified measurements. The heparinase-modified measurements, whether temperature-adapted or not, were not different compared with the corresponding native measurements before heparin administration. This shows that heparinase *per se* does not affect TEG and correlates with the findings of other investigations.[8 17]

The heparinase-modified TEG provides useful additional information compared with native TEG. At the end of surgery, after heparin reversal with protamine, nine cases of heparinase-modified TEG were improved compared with native TEG (fig. 7, table 2). These TEG measurements showed remaining heparin effects, which can increase bleeding after CPB. Comparison of native with heparinase-modified TEG is a useful guide when reconsidering protamine therapy after CPB.

In summary, our data showed reductions in coagulation caused by hypothermia, indicating the high sensitivity of TEG to temperature. Heparinase-modified TEG detected heparin effects remaining after heparin reversal with protamine. This could provide a rational guide to protamine therapy after CPB.

Benefits of intraoperative skin surface warming in cardiac surgical patients

L. HOHN, A. SCHWEIZER, A. KALANGOS, D. R. MOREL, M. BEDNARKIEWICZ AND M. LICKER

Summary

We have investigated patients undergoing cardiac surgery with hypothermic bypass to see if the addition of skin surface warming during systemic rewarming on bypass (heated group, n = 43) would improve perioperative thermal balance compared with conventional management without skin warming (control group, n = 43) in an open, randomized, controlled study. Intraoperative skin warming with a water mattress and forced warm air over the face, neck and shoulders attenuated the afterdrop in nasopharyngeal temperature after weaning from bypass (2.3 (1.2) °C and 1.3 (0.5) °C in the control and heated groups, respectively) (P < 0.05) and resulted in higher rectal temperature 4 h after surgery. Despite similar standard coagulation tests, heated patients had lower blood loss via the chest tubes (600 (264) ml *vs* 956 (448) ml in control patients) (P< 0.05) and less requirements for i.v. colloid infusion (1662 (404) ml *vs* 1994 (389) ml) (P < 0.05). There was a significant inverse correlation between rectal temperature on arrival in the ICU and postoperative blood loss (r = 0.57, P < 0.001). These data suggest that additional skin surface warming with a water mattress and forced warm air helped to preserve perioperative thermal balance and may contribute to reduced bleeding after cardiac surgery. (*Br. J. Anaesth.* 1998; **80**: 318–323)

Keywords: temperature, body; equipment, warming devices; surgery, cardiovascular; blood, coagulation; hypothermia

Hypothermia remains a common problem because of its deleterious haemodynamic, haemostatic, immune and metabolic effects.[1–4] After non-cardiac surgery, mild hypothermia has also been associated with arterial hypertension and myocardial ischaemia,[5] in addition to increased blood loss.[6]

Patients undergoing cardiac surgery are often cooled to nasopharyngeal temperatures of 26–28 °C. At the end of cardiopulmonary bypass (CPB), even though nasopharyngeal temperature is restored to pre-bypass levels, a considerable mass of peripheral tissues remains at subnormal temperatures; subsequent redistribution of heat from the core to the periphery causes a decrease in nasopharyngeal temperature ranging from 1 to 3 °C, termed "afterdrop".[7 8] During operation, adopting a "normothermic" bypass technique, prolonging the rewarming period or infusing vasodilators while increasing pump flow may attenuate the postoperative central temperature afterdrop.[9] In the intensive care unit (ICU), external heat, that is convective or radiant, applied over a large body surface area has been shown to accelerate rewarming with the benefits of less shivering, lower oxygen demand and more haemodynamic stability.[10–13]

Although skin surface warming with a forced warm air device is a simple, safe and efficient means for preventing hypothermia during major surgical procedures,[14] it has not yet been recommended for use during cardiac surgery because the body surface area available for cutaneous warming was thought to be too small.

As the afterdrop in nasopharyngeal temperature is attributed to redistribution of heat from the warm core to the cold peripheral compartment, we hypothesized that the addition of skin warming to heat exchange via the bypass membrane would improve body rewarming and help to preserve body heat content, thereby minimizing the afterdrop in core temperature. Therefore, we investigated if concomitant intraoperative use of a heating water mattress and forced warm air over a limited body surface area (head and neck) would effectively prevent hypothermia and attenuate chest blood loss in the early period after cardiac surgery.

Patients and methods

After obtaining hospital Ethics Committee approval and written informed consent, we studied 91 patients undergoing elective coronary artery bypass graft surgery, aortic valve replacement and mitral valve repair or replacement. Patients with severe left ventricular dysfunction based on clinical history (dyspnoea grade 3 or higher) and ventricular angiograms (left ventricular ejection fraction <30%) were excluded. In addition, in the early postoperative period, those patients with active bleeding requiring surgical haemostasis were retrospectively excluded. Usual cardiac medications, including nitrates, β-blockers and calcium channel blockers were administered up to the morning of surgery. After an overnight fast, patients were premedicated with morphine 7.5 mg i.m. and diazepam 5–10 mg orally, 1 h before opera-

tion. In the induction room, peripheral venous, radial arterial and central venous catheters were inserted for fluid and drug administration and for haemodynamic monitoring. A transoesophageal echocardiographic probe was inserted after tracheal intubation. General anaesthesia was conducted according to standard practice by an experienced anaesthetist not involved in the study and was based on moderate doses of fentanyl (40–60 μg kg^{-1}) and midazolam (0.03–0.06 mg kg^{-1} followed by 0.10 mg kg^{-1} h^{-1}) with pancuronium for neuromuscular block (0.15 mg kg^{-1} at induction and 0.05 mg kg^{-1} during bypass). Mechanical ventilation was adjusted to maintain normocapnia and normoxia. Body temperature was recorded continuously with calibrated thermistors (AS3 Datex Instrum. Corp. Helsinki, Finland) placed in the nasopharynx and in the rectum; nasopharyngeal and rectal temperatures indicated the temperature of the body core and muscular compartments.[8] All probes were accurate to ± 0.1 °C over the range 20–40 °C.

After aortic and right atrium cannulation, nonpulsatile CPB was commenced with a membrane oxygenator primed with crystalloids 2 litre and body temperature was decreased to achieve moderate hypothermia (lowest nasopharyngeal temperature 28.6 (2.4) °C and 28.9 (2.9) °C in the control and heated groups, respectively). After aortic clamping, myocardial protection was provided with St Thomas's solution 600–900 ml infused via the aortic root at 25–30-min intervals. During CPB, pump flow greater than 2 litre min^{-1} m^{-2} was maintained during moderate hypothermia and increased to 2.4 litre min^{-1} m^{-2} during rewarming. Vasodilators (nitroprusside) or vasoconstrictors (phenylephrine) were administered to maintain mean arterial pressure (MAP) within an acceptable range (60–80 mm Hg). After completion of surgical revascularization or valve repair–replacement, and when rectal temperature was greater than 35.7 °C, patients were weaned from CPB. Administration of nitroglycerin 1–3 mg h^{-1} i.v. was part of our standard management procedure, which was started during rewarming and continued until 6–8 h after surgery.

In the ICU, patients underwent mechanical ventilation throughout the 12-h study and, according to routine medical care, repeated bolus doses of morphine 1 mg were given during emergence from anaesthesia and when increases in heart rate and arterial pressure were interpreted as pain, anxiety or discomfort.

During and after operation, a heat and moisture filter (Pall breathing system, Newquay, UK) was connected to the Y-piece of the non-rebreathing respiratory system. Ambient temperature was maintained at 18–20 °C in the operating theatre and at 22–24 °C in the ICU.

MEASUREMENTS AND CALCULATIONS

During operation, nasopharyngeal and rectal temperatures were recorded at the following times: 10–15 min before aortic cannulation; at the end of each cardioplegia; after aortic unclamping; after separation from CPB; and during sternal and skin closures. Total duration of rewarming on bypass was recorded and the afterdrop was calculated as the difference between nasopharyngeal temperature at the time of separation from CPB and the lowest nasopharyngeal temperature recorded before transfer to the ICU.

After operation, activated clotting time and platelet count were measured on arrival in the ICU; systemic haemodynamic variables (MAP, heart rate, cardiac output) and rectal temperature were recorded hourly for 8 h and at 10 and 12 h after the end of surgery.

Urinary volume, blood loss through the chest tubes, i.v. fluid requirements (crystalloids and colloids), transfusion of blood products and the need for additional vasodilators (nitroprusside) and inotropic support (dobutamine or dopamine >5 μg kg^{-1} min^{-1}, norepinephrine or epinephrine >0.05 μg kg^{-1} min^{-1}) were also recorded.

EXPERIMENTAL DESIGN

On the day of surgery, patients were allocated randomly to routine thermal management (control group) or to additional skin warming (heated group). In both groups, core body rewarming (systemic rewarming) was accomplished by heat exchange through the oxygenator (maximum gradient of 10 °C between the patient's blood temperature and water temperature in the oxygenator). In the heated group, extra warming of the skin included transfer of convective heat with a Bair Hugger system (Bair-Hugger Model 500, Augustine SA, Berne, Switzerland) and conductive heat with a thermostatic water mattress (Thermostat T1000, JMW Medical Systems Ltd, Midlothian, UK). Heated patients lay on a mattress containing circulating water at 38 °C (5 litre with a mean flow of 3–4 litre min^{-1}) in contact with approximately 0.3–0.4 m^2 of body surface area (from the buttocks up to the shoulders) while forced warm air (at 38 °C) created a high velocity "wind" over the head, neck and shoulders (10–15% of body surface area) under a simple blanket. Systemic and skin rewarming were started during completion of the last distal graft anastomosis or at the end of valvular repair. Systemic rewarming ended when rectal temperature had reached 35.7 °C in the two groups, while skin rewarming was continued until skin closure (in the heated group).

In the ICU, nurses and physicians administering fluids and treating pain were blinded to the patient's group.

STATISTICAL ANALYSIS

Parametric data were expressed as mean (SD) and analysed using two-way analysis of variance with Dunnett's test for within-group changes with respect to baseline. The relationships between chest tube fluid losses (dependent variable) and other independent variables, such as rectal temperature, afterdrop, length of CPB and aortic clamping were studied by uni- and multiple stepwise regression analysis. Pearson product-moment or Spearman rank correlation coefficients were calculated depending on the parametric or non-parametric nature of the data. Drug treatment, need for transfusion and type of surgery were compared using chi-square with Yates' correction. Differences were considered significant at $P < 0.05$.

Results

We studied 91 patients; two patients in each group were subsequently excluded because of bleeding which required surgical haemostasis within the first 3 h after operation. Another patient in the control group died within 2 h after surgery in cardiac failure as a result of a massive myocardial infarct.

Preoperative clinical, surgical and anaesthetic data are summarized in table 1. The two groups were similar in patient characteristics and surgical data. The risk of bleeding, as indicated by the type of surgery (combined valvular surgery and myocardial revascularization) and the use of aprotinin or antiaggregant and anticoagulant medications were also comparable in the two groups. Activated clotting time and platelet count were similar on arrival in the ICU, in addition to packed cell volume at the end of the study. Postoperative shivering requiring administration of pethidine or a muscle relaxant was observed in five patients in the heated group and in nine patients in the control group.

PERIOPERATIVE BODY TEMPERATURE

Duration of systemic rewarming and the gradients between nasopharyngeal and rectal temperatures after weaning from CPB did not differ between the two groups (table 2). However, body temperature was better maintained in the heated group, as: (1) the afterdrop in nasopharyngeal temperature was smaller; (2) fewer patients presented with nasopharyngeal temperatures less than 35.5 °C at the end of surgery (15 and 28 patients in the heated and control groups, respectively) ($P < 0.05$); and (3) rectal temperature was significantly higher from the time of sternal closure up to 4 h after operation (fig. 1).

In the control patients, rectal temperature on arrival in the ICU was 35.3 (0.4) °C and increased at a rate of approximately 0.3 °C h^{-1}, whereas in the heated group, initial postoperative rectal temperature was 36.0 (0.4) °C and increased more slowly (approximately 0.2 °C h^{-1}) over the subsequent 6 h. At the end of the 12-h study, rectal temperatures did not differ between the two groups (37.5 (0.5) °C in the heated and 37.4 (0.5) °C in the control group).

There was no significant association between the afterdrop in nasopharyngeal temperature and aortic clamping time ($r = 0.12$), CPB duration ($r = 0.09$), lowest temperature during CPB ($r = 0.08$) or body surface area ($r = 0.25$) in the two groups. In the control group only, the afterdrop in nasopharyngeal temperature was significantly correlated with the ratio of rewarming time to duration of aortic clamping ($r = 0.86$); in these patients, duration of systemic rewarming, representing >80% or <80% of clamping time, was associated with an afterdrop in nasopharyngeal temperature of −1.7 °C or −2.5 °C, respectively.

HAEMODYNAMIC STATE

Haemodynamic data (heart rate, MAP and cardiac output) were comparable in the two groups in addition to requirements for inotropic or, vasopressor support (15 patients in the heated group and 20 patients in the control group) and for additional vasodilators (five patients in the heated group and seven in the control group). Nitroglycerin was administered at a median rate of 2 mg h^{-1} in the two groups and over a median period of 8 h in the control group and 7 h in the heated group.

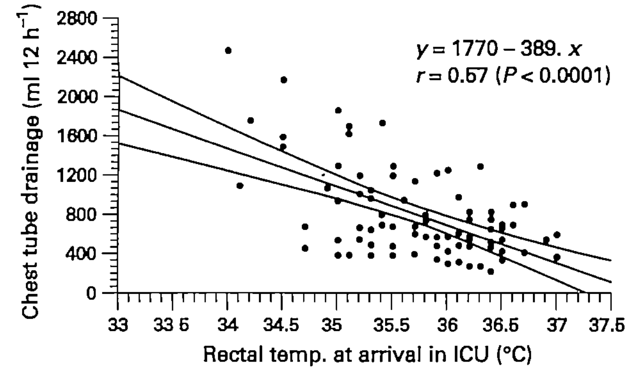

Figure 2 Relationship between fluid loss via the chest tubes over the first 12 h after cardiac surgery and rectal temperature on arrival in the ICU (regression line and 95% confidence intervals).

FLUID BALANCE AND HAEMOSTATIC VARIABLES

During operation, i.v. clear fluids, transfusion of homologous blood products and urine output did not differ between groups. During the first 12 h in the ICU, the amount of blood loss through the chest tubes was smaller in the heated group (−31%, $P < 0.05$) and was accompanied by reduced i.v. infusion of fluids (−23%, $P < 0.05$) compared with the control group (table 3). Transfusion of homologous blood components tended to be reduced in the heated group, although this was not significant (seven patients compared with 13 patients in the control group). There was a significant inverse relationship between rectal temperature on arrival in the ICU and postoperative fluid loss via the chest tubes in the pooled data for the two groups ($r = -0.57$, $P < 0.0001$). Regression analysis between these two variables is illustrated in figure 2.

Discussion

As expected, many patients became hypothermic at the end of cardiac surgery, despite systemic rewarming until rectal temperature reached at least 35.7 °C, and when no precautions were taken to avoid "redistribution hypothermia". In contrast, intraoperative combination of two simple skin warming methods (Bair Hugger and water mattress) in addition to core rewarming attenuated the core temperature afterdrop and resulted in higher rectal temperatures in the early hours after CPB. Importantly, better thermal homeostasis was associated with reduced postoperative fluid losses and i.v. fluid requirements.

Application of skin warming did not adversely affect the working conditions in the operating theatre compared with the routine management procedure. Additional noise was barely noticeable, i.v. cannulae were secured on the operating table, the patient's face and eyes were · checked regularly and the transoesophageal echocardiographic probe was manipulated easily.

THERMAL BALANCE

In unwarmed patients, a core temperature afterdrop of −2 °C has been associated with a heat deficit of more than 300 kJ which is equivalent to basal heat production over 1–2 h and requires 50–100% increase in energy expenditure in the early postoperative period.[7 15] In this study, we hypothesized that heat storage in peripheral tissues would reduce the core-to-periphery gradient and attenuate heat flow redistribution. In the heated group, skin warming with forced warm air and a water mattress resulted in a mean decrease in nasopharyngeal temperature of 39% less and a higher rectal temperature during the first 4 h in the ICU compared with control patients. Presumably, higher mean body temperature (+0.8 °C compared with the control group) was associated with better restoration of body heat content after weaning from bypass (approximately +195 kJ in a 70-kg adult) and with diminished thermoregulatory responses to cold, as indicated by a slower postoperative increase in rectal temperature in heated patients (0.2 °C h^{-1} compared with 0.3 °C h^{-1} in control patients).

During non-cardiac surgery, when 80–90% of the body surface is exposed to forced warm air (38 °C), a large amount of heat (approximately 200 kJ h^{-1}) has been shown to be transferred across the skin.[16] During cardiac surgery, despite a smaller surface available (only 10–15% of the total body surface), transfer of convective heat was likely facilitated by several factors, namely the underlying highly perfused anatomic structures of the upper body, large air–skin temperature difference, prolonged duration of rewarming (2–2.5 h) and a high velocity convective "wind". Interestingly, heat transfer has been shown to be twice as effective when forced air is delivered beneath a simple bed sheet instead of using a commercial blanket whose rigid nature prevents the close approximation to non-planar anatomical structures and whose pinhole gridwork pattern causes low flow velocity.[17]

Conductive heat flow was also transfered across the larger skin surface in contact with the warm water mattress (approximately 0.3–0.4 m^2). Its modest rewarming efficiency in non-cardiac surgery has been attributed to the relatively small surface available and to poor perfusion in dependent areas.[18] Although many centres currently use a circulating water mattress in adult cardiac surgery, there is no clear evidence concerning its beneficial effects in terms of heat balance when used as a sole adjuvant to core rewarming.

Nitroglycerin and high perfusion flow rates were used in all patients during systemic rewarming in order to increase heat delivery to the "cold" muscles and thereby expand the "warm" body core. Hence in the two groups pharmacological vasodilatation contributed to the attenuation in subsequent redistribution hypothermia (as heat can only flow down a temperature gradient). As reported previously by Noback and Tinker,[9] the afterdrop in nasopharyngeal temperature in control patients was related to the ratio between duration of systemic rewarming and hypothermic clamping: if systemic rewarming was prolonged >80% of clamping time, the afterdrop in nasopharyngeal temperature was attenuated. In this regard, additional skin surface warming could help to reduce the rewarming time on bypass.

TEMPERATURE AND HAEMOSTASIS

Chest fluid drainage consists of blood oozing from the surgical wound that is mixed with residual ice-slush solution and transudated fluids from the visceral pleura. An important observation was a significant correlation ($r = -0.57$) between postoperative blood loss via the chest tubes and rectal temperature on arrival in the ICU. This could explain approximately 33% of the relationship between these two variables, and the slope of the linear regression equation predicts an average additional fluid loss of 389 ml $°C^{-1}$ over a range of rectal temperatures from 37 to 34 °C. Except for the difference in rectal temperature, all other factors that would affect postoperative bleeding (i.e. activated clotting time, platelet concentration and administration of antiaggregant, nitrates and aprotinin) were similar in the two groups.

Unless considered specifically, the contribution of hypothermia to haemorrhagic diathesis is overlooked in clinical practice as standardized procedures for coagulation testing are performed at 37 °C and the number of platelets is unaffected by cold.[19] The disparity between near-normal *in vitro* clotting studies and clinically non-surgical bleeding can be attributed to both coagulation and cold-induced platelet dysfunction. First, the process of coagulation involves a series of enzymatic reactions and the speed at which these reactions occur is temperature-dependent; prothrombin and activated partial thromboplastin times are increased by approximately 10–15% when temperature decreases from 37 to 34 °C.[20 21] Second, cold-induced activation of the fibrinolytic system can further impair the haemostatic capacity, but to a much lesser extent.[22] Third, prolongation of bleeding time during mild hypothermia is caused by a defect in the ability of platelets to produce thromboxane A_2, a proaggregatory factor, at the bleeding site.[23] In heated patients, the beneficial effects of skin warming in terms of reduced bleeding were more likely attributed to better preservation of platelet function as local rewarming has been demonstrated to normalize both bleeding time and platelet aggregation.[23 24]

LIMITATIONS OF THE STUDY

In this study, extra skin warming resulted in higher rectal and nasopharyngeal temperatures in heated patients undergoing surgery of long duration with hypothermic bypass. However, we were unable to measure heat fluxes because surgical incision precluded positioning of skin temperature probes over the thorax, legs and arms. Furthermore, it is not known if extra skin warming is (more or less) beneficial during shorter surgical procedures, under normothermic conditions or in selected patients with co-morbidities (i.e. obesity, heart failure).

The amount of postoperative blood loss varies largely among different centres and reproduction of the study results depends on the adoption of similar medical management procedures. All patients were given nitroglycerin and nitroprusside which may cause impairment of lung oxygenation and exert an antiplatelet effect via increase in cyclic guanidine monophosphate and reduction of proaggregatory endoperoxide and thromboxane A_2.[25] However, nitrate-induced postoperative bleeding is questionable in the context of major surgery as high plasma concentrations of epinephrine have been shown to reverse nitrate-induced platelet inhibition.[26]

Although we observed a similar haemodynamic pattern in heated and control patients, we did not evaluate myocardial ischaemia or plasma concentrations of catecholamines which could provide a better indication of hypothermia-induced stress. Nevertheless, in the context of cardiac surgery, it is likely that activation of the sympatho-adrenal and renin–angiotensin systems, in addition to the release of vasopressin in response to surgical trauma, largely overwhelmed the mild physiological response that could be attributed to a small difference in nasopharyngeal temperature (0.8 °C).[27 28]

In summary, mild postoperative hypothermia is known to be associated with bleeding diathesis and increased oxygen demand. Our data suggest that intraoperative skin warming with a water mattress and forced warm air over the patient's face, neck and shoulders is a simple and efficient means of reducing the temperature afterdrop after hypothermic CPB and reducing postoperative blood loss. Complete rewarming of the body contributes to improved quality of perioperative care, allowing fast recovery while potentially reducing perioperative respiratory morbidity.[29] In our institution, the standard perioperative management for most cardiac surgical patients has evolved with the use of additional skin warming and short-acting anaesthetics. Such strategies are aimed at achieving earlier tracheal extubation and shorter duration of ICU stay, thereby reducing medical costs.

Pharmacokinetics of propofol during conscious sedation using target-controlled infusion in anxious patients undergoing dental treatment

V. L. B. OEI-LIM, M. WHITE, C. J. KALKMAN, F. H. M. ENGBERS, P. C. MAKKES AND W. G. OOMS

Summary

Infusion of propofol by a target-controlled infusion (TCI) system is effective in achieving conscious sedation for anxious patients presenting for dental surgery. It is a common clinical observation that anxious patients require more anaesthetic drugs than non-anxious individuals. In study 1 we have defined blood propofol concentrations necessary for conscious sedation in both anxious ($n = 23$) and non-anxious ($n = 18$) patients. The pump performance of the TCI system, using Gepts' pharmacokinetic model, was evaluated in these two patient groups. Subsequently, clearance of propofol was compared in the two groups. Mean measured venous serum propofol concentrations obtained between 20 and 35 min after the optimal sedation level was reached were 1.6 (SD 0.2) μg ml^{-1} in the anxious patients compared with 1.7 (0.3) μg ml^{-1} in the control group (study 1) and 1.4 (0.27) μg ml^{-1} in study 2. The pump systematically overpredicted measured propofol concentrations in both groups (study 1). There was no significant difference in propofol clearance between the two groups. In study 2, an optimized set of microconstants was derived which should more accurately predict the pharmacokinetic profile of the anxious population and this set was tested prospectively in another group of 12 anxious dental patients. Bias and precision with the optimized kinetic set were significantly less than the values obtained in study 1. We conclude that there was no significant pharmacokinetic differences between anxious and non-anxious subjects receiving subanaesthetic doses of propofol for conscious sedation. (*Br. J. Anaesth.* 1998; **80**: 324–331)

Keywords: anaesthetics I.V., propofol; pharmacokinetics, propofol; surgery, dental; psychological responses

When administered in subanaesthetic doses, propofol has useful sedative and anxiolytic properties. Infusion of propofol by a target-controlled infusion (TCI) system has been shown to be effective in achieving conscious sedation for extremely anxious and mentally handicapped patients presenting for dental surgery.[1] A TCI system consists of a computer-controlled infusion pump which uses pharmacokinetic models in the calculation and delivery of infusion regimens required to theoretically achieve and maintain stable concentrations of drug in the patient.[2–5]

The first objective of this study was to define the blood propofol concentrations necessary for conscious sedation in both anxious and non-anxious patients presenting for dental chair surgery. It is a common clinical supposition that anxious patients have a greater requirement for anaesthetic drugs than non-anxious patients and we wished to establish if there was a difference between the two groups in the target concentrations at which satisfactory sedation conditions were achieved. The second objective of the study was to evaluate the performance of a target-controlled propofol infusion system using the three-compartment pharmacokinetic model proposed by Gepts and colleagues[6] during conscious sedation in these two patient groups. We subsequently analysed the relationship between measured serum propofol concentrations and the drug input regimens used by the TCI system in the two patient populations and determined and compared the clearance of propofol in the two groups. Thereafter, we derived an optimized set of microconstants which should, at least in theory, more accurately predict the pharmacokinetic profile of the anxious patient population. In a second study the performance of this refined kinetic set was tested prospectively in another 12 anxious subjects undergoing similar dental procedures (study 2).

Patients and methods

The study was approved by the Institutional Ethics Review Board of the Academic Hospital, University of Amsterdam. Children, pregnant women, patients aged more than 65 yr or ASA III or IV, or body mass index >28 kg m^{-2} were excluded from the study. Use

of concomitant medication, abuse of alcohol and allergy to propofol or soya beans were additional criteria for exclusion.

STUDY 1

We studied 23 patients (12 females, 11 males) (anxious group), ASA I or II, undergoing routine dental chair procedures. All gave informed consent to undergo the procedure under conscious sedation with propofol. These patients had been referred to the clinic because of inability to comply with dental surgery without sedation because of associated anxiety. All patients fulfilled the criteria for anxiety, as assessed using the unidimensional Corah's dental anxiety scale (DAS). DAS scores of 15–20 are an indication of anxiety[7] whereas a DAS score <10 is considered as non-anxious. A non-anxious control group (*n* = 18, nine males, nine females), undergoing extraction of one or more molars volunteered to undergo the procedure with conscious sedation. The characteristics of these two groups are shown in table 1.

No premedication was given. Articaine–epinephrine was administered for local anaesthesia when the procedure was expected to be painful. No other anaesthetic or analgesic drug was administered.

Delivery system

The TCI system was designed by one of the authors (F. E.). The program runs on a microcomputer connected to a Graseby 3400 infusion pump (Graseby Medical Ltd, Watford, UK) via an RS-232 serial interface. The computer program used a three-compartment mathematical model to calculate continuously the distribution of propofol. Pharmacokinetic microconstants derived by Gepts and colleagues[6] (table 2) were incorporated into the computerized delivery system. The initial target concentration was entered into the computer before the start of sedation. The anaesthetist could manipulate the predicted concentration in any direction at any time. Induction of sedation was achieved by rapid infusion at a rate of 700 ml h^{-1} and thereafter the computer automatically delivered an infusion regimen that was calculated to maintain the target concentration constant. Predicted blood propofol concentrations, together with the propofol infusion rate, were stored on disk every 30 s. In addition, patient number, sex, age, ASA status and weight, together with details of the infusion profile, were stored within the disk file created by the TCI pump.

2. Drowsy	Mood alteration, not yet fully cooperative
3. Eyes closed, responds promptly to verbal commands	Cooperative, allows treatment to be performed
4. Eyes closed, rousable on mild physical stimulation only	
5. Eyes closed, unrousable on mild physical stimulation	

Sedation procedure

After obtaining baseline recordings of the electrocardiogram (ECG), heart rate (HR), non-invasive arterial pressure (NIAP) and oxygen saturation (Sp_{O_2}), a standardized conscious sedation regimen was initiated. An infusion of propofol with a preset target concentration of 2.5 µg ml^{-1} (study 1) was started until the patient had reached the desired clinical end-point of sedation. A five-point sedation scale was used (table 3). The aim was to reach and maintain sedation level 3. In addition, cooperation and treatability was an end-point in the anxious groups (table 3). If these clinical end-points were not reached within 3 min (inadequate sedation), the target concentration was increased, in steps of 0.2 µg ml^{-1}, until treatment could be performed. When sedation level 3 was reached, the propofol target level was maintained, unless signs of over sedation became apparent (sedation level 4), as indicated by diminished response to communication or decreasing (Sp_{O_2}). In that event the target concentration was decreased in steps of 0.2 µg ml^{-1} and the dental procedure halted temporarily until the desired sedation level was regained. When a disinhibitory type of over sedation was present (agitation, excitement, restlessness and lack of cooperation), the target concentration was decreased in the same way. Oxygen supplementation was not administered routinely. When patients were sedated adequately, a second venous access site for blood sampling for measurement of propofol concentrations was established in a large forearm vein contralateral to the site of infusion.

At the end of the dental treatment, propofol infusion was discontinued and the patient allowed to recover in the dental chair. Recovery of cognitive and psychomotor function after sedation was tested by recall of personal data and the Romberg test. When responses to these tests had returned to pre-sedation values, the patient was allowed to go home under appropriate escort.

Monitoring

NIAP was measured automatically every 5 min using a Critikon Dinamap (1846 SX) arterial pressure monitor. Heart rate and (Sp_{O_2}), were monitored continuously using a Criticare (504-US) pulse oximeter. A standard single-channel ECG was displayed on a Hewlett-Packard ECG monitor (78345A). Data collection started before sedation and continued until 5 min after discontinuation of propofol infusion. The ECG monitor, arterial pressure monitor and pulse oximeter were interfaced to a personal computer which stored on disk heart rate, systolic, diastolic and mean arterial pressures, and (Sp_{O_2}), at 30-s intervals, together with the time of recording. During the procedure, the dentist and anaesthetist continuously maintained verbal and non-verbal communication with the patient, and monitored the protective airway reflexes. The aim was to maintain sedation level 3 on the five-point sedation scale (table 3).

Venous blood sampling

Peripheral venous blood samples were obtained at the following times: 10 and 25 min after reaching the clinical end-point of sedation and at 15-min intervals thereafter. A sample was also obtained 10 min after discontinuing propofol infusion. The sampling arm was maintained at body temperature with a blanket and placed horizontally without constricting bands. No tourniquet was used during sampling. Arterial pressure was measured on the sampling arm and measurements were not performed within the 5-min period before sampling. The deadspace fluid in the cannula was removed before each sampling. Samples of blood (5 ml) were stored immediately in plain tubes at 4°C and clotted blood was centrifuged at the end of the day. Serum samples were stored at −20 °C until analysis within 30 days after collection. Propofol concentrations were assessed in duplicate by high performance liquid chromatography, as described by Plummer.[8] Accuracy of the essay was 0.48% at 2.02 $\mu g\ ml^{-1}$ and 1.46% at 4.04 $\mu g\ ml^{-1}$ The lower limit of detection was 0.025 $\mu g\ ml^{-1}$.

Computer analysis

Each measured blood concentration of propofol (C_m) was compared with the corresponding delivery system predicted target concentrations (C_P). In order to correct for the fact that the delivery performance of a TCI pump is never ideal,[9 10] the simulated concentration (C_{sim}) was calculated on the basis of the delivery system record of the infusion profile actually administered to each individual (as opposed to that which should have been given).

The percentage prediction error, calculated for each datum point was defined as:

$$\text{Prediction error } (PE_{ij}) = \frac{C_{m_{ij}} - C_{P_{ij}}}{C_{P_{ij}}} \times 100 \quad (1)$$

where $C_{P_{ij}}$ = *j*th prediction of the plasma drug concentration in the *i*th patient, and $C_{m_{ij}}$ = *j*th measurement of the plasma drug concentration in the *i*th patient.

Bias is defined as the median prediction error[11] and is a measure of the systemic tendency of the system to under or over estimate the measured concentration of blood propofol. If bias has a positive value, then the measured value is, on average, greater than the system prediction and vice versa.

$$\text{Median prediction error } (MDPE_i) = \text{median } \{PE_{ij}, j=1,\ldots, N_i\} \quad (2)$$

Precision is the median absolute performance error and is defined by:

$$(MDAPE_i) = \text{median } \{|PE_{ij}|, j=1,\ldots, N_i\} \quad (3)$$

where N_i = number of performance errors obtained in the *i*th individual.

Precision is a measure of the inaccuracy of the system.[11] Corrected values for each of the above values were calculated in an analogous manner by substituting C_{sim} for C_P. The ideal pharmacokinetic model for a delivery system produces minimum bias and precision values.[11] In order to derive a new set of pharmacokinetic variables which would more accurately predict measured blood concentrations in anxious patients, drug input and measured propofol plasma concentration data were analysed by a program (pharmacokinetic optimization (PKOPT)) that uses non-linear regression to minimize the extended least-squares objective function (NONMEM objective function (−2 log likelihood (-2LL)).[12 13] The program, developed by one of the authors (M. W.) was written in GFABasic for Windows (GFA Data Media (UK) Ltd) and runs in compiled form on an IBM 486 or a more powerful computer running either MS Windows 3.1/.11 or Windows 95. Data input is highly automated and consists of the computerized record of each infusion profile generated by the TCI pump, together with a pre-formatted file containing the measured blood propofol data. The program is capable of analysing data either from individuals or from a population (population approach). It derives a set of new population pharmacokinetic variables which significantly (by chi-square testing $P<0.01$) reduces the NONMEM objective function. The data obtained in study 1 were entered into the program, and a new set of microconstants was derived that should result in improved population bias and precision.

Clearance values of propofol for each individual in the study were calculated by obtaining the best fit to the measured propofol concentrations using the NONMEM objective function of the PKOPT program. The values thus obtained for the two patient groups were compared using the Mann–Whitney *U* test.

STUDY 2

The optimized kinetic dataset was tested prospectively in 12 highly anxious patients (five females, seven males) undergoing similar dental procedures. The target concentration was adjusted to obtain the same clinical end-point. To account for the anticipated reduced bias, the initial target concentration was set to 1.4 $\mu g\ ml^{-1}$. In study 2, venous blood samples were obtained every 15 min after patients were

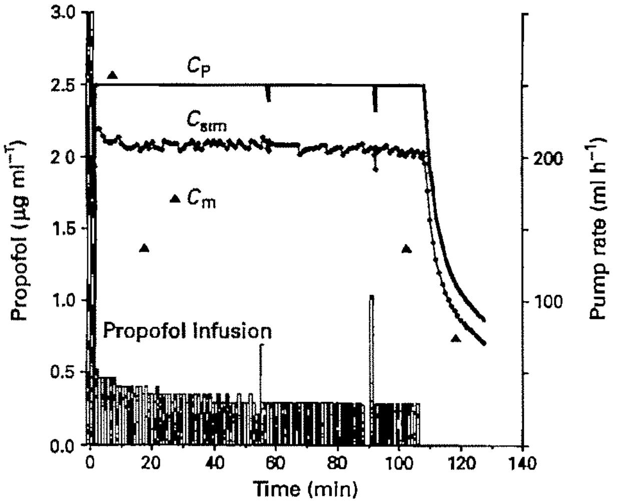

Figure 1 Course of sedation in a representative anxious female patient (aged 34 yr, weight 59 kg) The figure depicts propofol concentration predicted by the pump algorithm (C_P), the corresponding calculation based on re-simulation of the actual drug delivery profile (C_{sim}) and measured serum propofol concentrations (C_m). The increases in infusion rates at 55 and 90 min are because of replacement of a near empty syringe with a replacement filled syringe. The propofol infusion rate is also indicated.

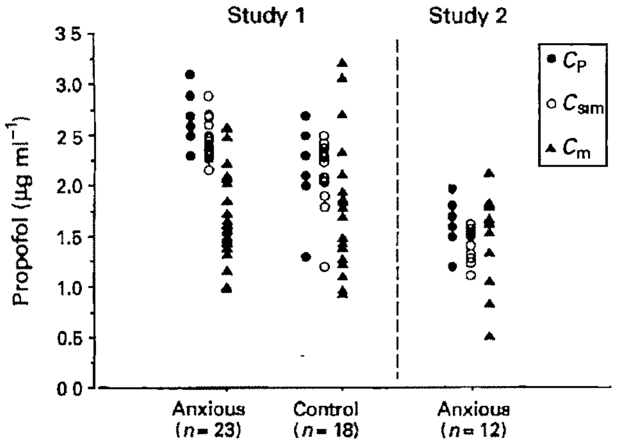

Figure 2 Propofol concentrations during conscious sedation in study 1 (anxious $n = 23$ and control $n = 18$) and study 2 (anxious $n = 12$) predicted by the pump algorithm (C_P), the corresponding calculation based on re-simulation of the actual drug delivery profile (C_{sim}) and measured serum propofol concentrations (C_m).

sedated adequately and 10 min after discontinuation of propofol infusion.

Data are presented as mean (SD), median (10th–90th percentiles) or median [range]. The pharmacokinetic performance of the various models was compared by chi-square testing of the calculated NONMEM objective functions. Probability values less than 0.05 were considered significant.

Results

STUDY 1

Figure 1 illustrates the course of sedation for a typical individual in the anxious group. An initial target of 2.5 µg ml⁻¹ was selected and, in this particular case, was deemed satisfactory for the entire course of the dental procedure. At the end of the procedure, the infusion device was turned off and the patient was allowed to recover while the predicted concentration of propofol in the patient's blood continued to be calculated by the delivery device algorithm. The measured values of serum propofol are overlaid on the system record of predicted concentration (C_P) and infusion regimen, together with the re-simulated or corrected profile based on the record of the infusion profile obtained from the pump's data file. Re-simulation revealed that the performance of the pump was less than ideal and that the corrected predicted values were somewhat less (8–10%) than those predicted by such ideal pump performance.

Table 4 Sedation data (mean (SD) [range])

	Study 1 Anxious patients	Study 2 Non-anxious control patients	Study 2 Anxious patients
Duration of infusion (min)	63 (23) [26–116]	43 (17) [25–94]	83 (37) [56–188]
Preset target propofol concentration (C_P) (µg ml⁻¹)	2.63 (0.1) [2.3–3.1]	2.4 (0.2) [1.3–2.7]	1.63 (0.1) [1.2–1.8]
Simulated blood propofol concentration (C_{sim}) (µg ml⁻¹)	2.39 (0.07) [2.1–2.84]	2.12 (0.15) [1 15–2.45]	1.36 (0.1) [1.06–1.57]
Measured serum propfol concentration (C_m) (µg ml⁻¹) at 20–35 min during optimal sedation level	1.65 (0.2) [0.93–2.52]	1.73 (0.3) [0.87–3.15]	1.42 (0.27) [0.45–2.07]
Dose rate (mg kg⁻¹ h⁻¹)	7.1 (0.8) [5.9–8.7]	7.1 (1.0) [4.5–8.7]	4.89 (1.7) [6.3–6.7]
Total dose (mg h⁻¹)	513 (167) [316–957]	490 (83) [338–658]	410 (98) [295–607]
No. of blood samples	5.7 (0.9) [4–7]	4.5 (0.9) [2–6]	5.7 (1.7) [4–9]

Sedation data are presented in table 4 and figure 2. The mean target concentration (C_P) necessary to maintain sedation level 3 in anxious patients was 2.6 (0.1) [range 2.3–3.1] µg ml⁻¹ (re-simulated values (C_{sim}) 2.4 (0.07) [range 2.1–2.8] µg ml⁻¹). Measured serum propofol concentrations (C_m) obtained between 20 and 35 min after the optimal sedation level was reached were 1.65 (0.2) µg ml⁻¹ in anxious patients compared with 1.73 (0.3) µg ml⁻¹ in the non-anxious control group. Mean duration of drug input was 63 [range 26–116] min. In the non-anxious control group, mean target concentration (C_P) at which satisfactory sedation was achieved was 2.4 (0.2) [range 1.3–2.7] µg ml⁻¹ (re-simulated values 2.12 (0.15) [range 1. 15–2.45] µg ml⁻¹). Mean duration of infusion was 43 [25–94] min. Transient over-sedation occurred in two patients in the anxious group and in three patients in the non-anxious control group.

Figure 3A shows the scatterplot of the percentage prediction errors compared with the corresponding simulated concentration for the two groups. The corrected median prediction error (bias) calculated for the anxious population was −32.4% compared with −22.2% in the non-anxious control group. Precision was 33.7% in the anxious population and 28.3% in the non-anxious control group. Therefore, in both groups the pump systematically overpredicted measured propofol concentrations. The time related course of prediction error for each individual in the

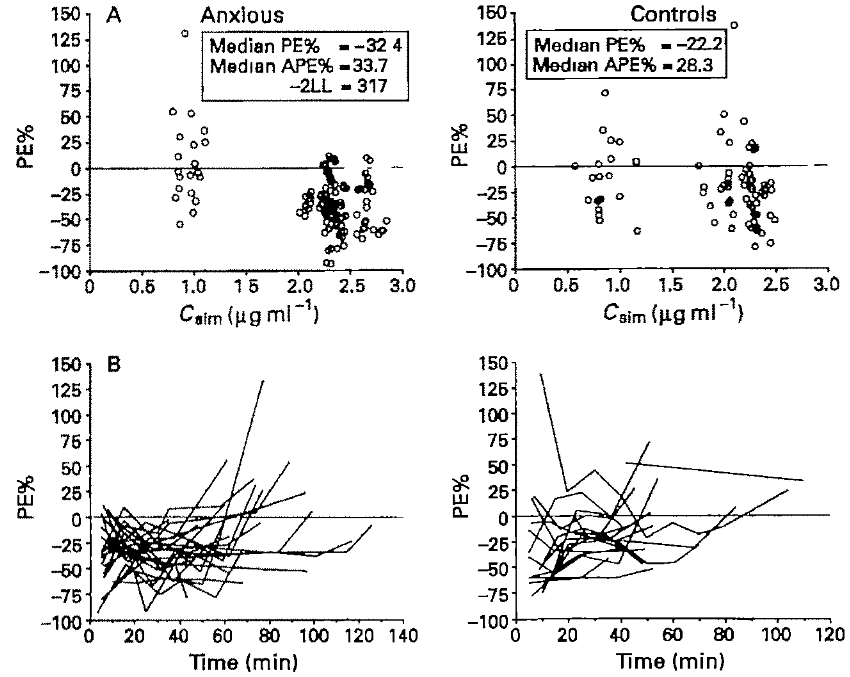

Figure 3 A: Percentage prediction error (PE%) *vs* predicted propofol concentration (C_{sim}) based on re-simulation using the actual amount of propofol and the pharmacokinetic microconstants published by Gepts and colleagues[6] delivered by the TCI system in anxious and control patients. B: Percentage prediction error (PE%) *vs* time for each patient in the anxious and control groups.

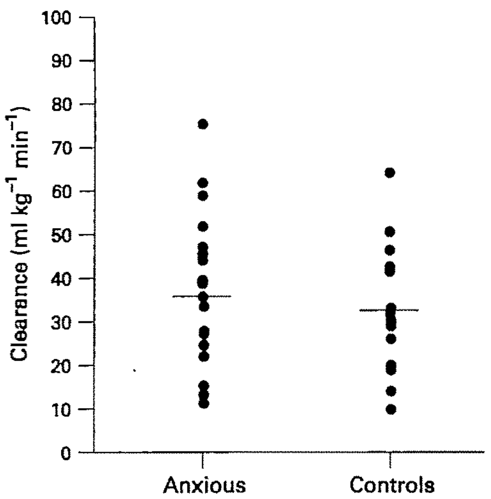

Figure 4 Individual propofol clearance values in the anxious and control patients (study 1) determined by obtaining the best fit to the measured propofol concentrations using the NONMEM objective function of the PKOPT program. Horizontal bars indicate median values.

two groups is shown in figure 3B. There was no significant difference in propofol clearance between the two groups (fig. 4). Median clearance was 36.0 (11.9–62.1) ml kg^{-1} min^{-1} in anxious patients and 31.7 (13.9–50.5) ml kg^{-1} min $^{-1}$ in non-anxious control subjects.

STUDY 2

The data obtained from the anxious group in study 1 were entered into the PKOPT program and a new set of population microconstants (table 2) was derived which significantly minimized ($P < 0.01$) the NONMEM objective function for the experimental data from study 1 and which should result in improved pump performance. For each measurement of blood propofol a new prediction error was calculated on the basis of a new predicted value based on the new pharmacokinetic model derived by the computer program. The values of bias and precision calculated on the basis of the new optimized model were 0.02 and 25%, respectively (fig. 5A) The NONMEM objective function (−2LL) was reduced from 317 to 195. No additional improvement in the objective function was obtained by an additional regression step to include patient age.

The refined microconstants were then used to update the TCI pump delivery program and both the clinical and pharmacokinetic performance of this system were assessed prospectively in a second group of 12 patients. The clinical data are shown in table 4. No oversedation was encountered with the modified pharmacokinetic settings in any patient. The target propofol concentration in study 2 necessary to maintain sedation level 3 was 1.6 (0.1) [range 1.1–1.9] μg ml^{-1} (re-simulated values 1.36 [range 1.06–1.57] μg ml^{-1}) (fig. 2). Mean duration of propofol delivery was 83 (37) [range 56–188] min. Measured serum propofol concentration obtained between 20 and 35 min after reaching the optimal sedation level was 1.42 (0.27) μg ml^{-1}. The time course of pump predictive performance is shown in figure 5B. Median prediction error (bias) after re-simulation was −5.0% and precision was 16%. Bias and precision with the optimized kinetic set were significantly ($P < 0.01$) less than the values obtained in study 1. A mean of 2 (range 0–3) alterations in target concentrations were made in all patients.

In all patients, haemodynamic and (Sp_{O_2}), indices were stable and there were no instances of deviation greater than 15% from baseline.

Discussion

In study 1, the measured serum propofol concentration necessary to maintain the optimal level of sedation in our study was approximately 1.5 μg ml^{-1}, and

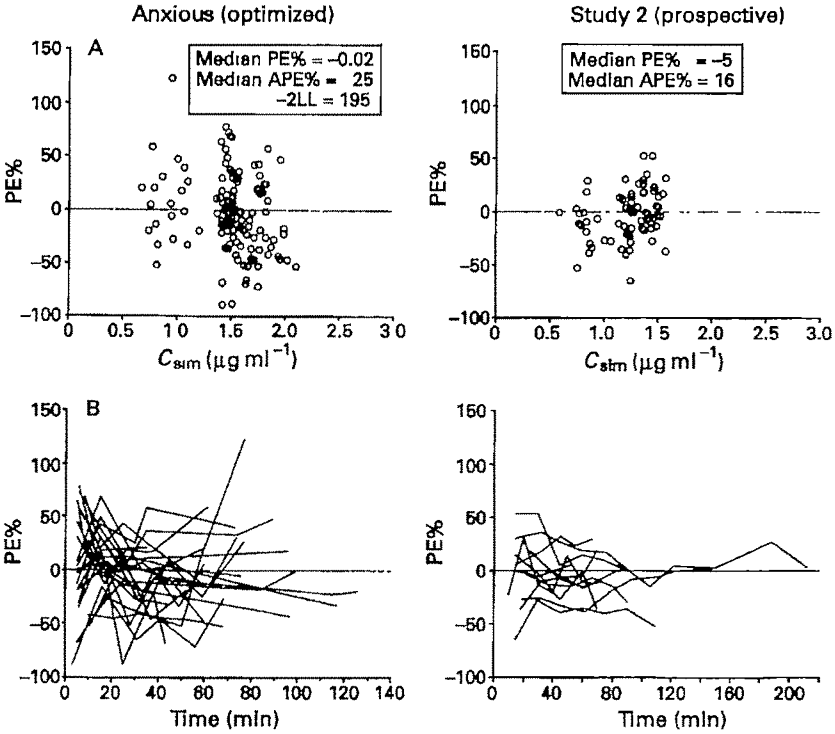

Figure 5 A: Percentage prediction error (PE%) *vs* predicted propofol concentration (C_{sim}) based on re-simulation using the actual amount of propofol delivered and the optimized pharmacokinetic microconstants derived with PKOPT program in anxious patients from study 1 and anxious patients in the prospective study 2. B: Percentage prediction error (PE%) *vs* time for each individual, using the optimized pharmacokinetic microconstants derived with the PKOPT program in anxious patients from study 1 and anxious patients in the prospective study 2.

there were no significant differences between anxious and non-anxious control patients. In study 2, similar serum propofol concentrations were measured in anxious patients using the optimized kinetic data set, despite lower target concentrations being set on the modified TCI system. The results of study 1 revealed no evidence to support the existence of a difference in propofol clearance between anxious patients and non-anxious controls.

For study 1, in both anxious and non-anxious subjects receiving subanaesthetic doses of propofol via a target-controlled infusion system using Gepts' kinetic dataset, measured values of propofol were systematically overestimated by the delivery system model. The clinical setting in which Gepts' microconstants were derived[6] differed considerably from the conditions in our study involving dental outpatients, and these differences may partly explain the large negative bias observed in our study. Gepts' parameter set was derived from three groups of six patients who were older than the dental patients and volunteer subjects in our study. Propofol was administered as a constant rate infusion for at least 2 h at a rate of 3 μg ml^{-1} h^{-1} in patients aged approximately 60 yr, 6 μg ml^{-1} h^{-1} in patients aged 50 yr and 9 μg ml^{-1} h^{-1} in patients aged 40 yr, who underwent urological procedures under spinal or local anaesthesia. The infusion rates necessary to maintain conscious sedation in our dental patients and volunteers were of the order of 4.5–8.7 μg ml^{-1} h^{-1}. Lastly, in Gepts' analysis, arterial sampling was performed, whole blood samples were collected and whole blood propofol concentrations were determined whereas in our study, sampling was from a venous site and serum propofol concentrations were measured.

We opted to obtain venous samples to minimize discomfort and risk in our highly anxious patients. The decision to use venous rather than arterial blood samples may have resulted in lower measured blood propofol concentrations compared with Gepts' study. During a bolus and infusion regimen that achieves and maintains a constant arterial concentration, it may be expected that the AV differences are greatest initially as drug is distributed rapidly into the tissues. This difference diminishes as the tissues become saturated, until after some minutes arterial and venous concentrations are the same. Chiou[14] demonstrated that at steady state during constant infusion, there was no difference in arterial and venous blood (plasma) concentrations during the dosing interval as peripheral tissue uptake of propofol is zero. Coetzee and colleagues[15] suggested that in evaluating propofol TCI, it is preferable to use arterial concentrations, but venous concentrations can be used too, bearing in mind that propofol venous concentrations are lower than arterial values and that sampling should be performed several minutes after adjustment to the targeted concentration. Because we obtained venous blood 10 min after reaching the clinical end-point of sedation (at least 15 min after the start of infusion), it is unlikely that the difference between arterial and venous blood propofol concentrations was sufficient to explain the observed negative bias. We have determined propofol concentrations in serum. Propofol concentrations in whole blood, plasma or serum may differ. Coetzee and colleagues[15] compared propofol concentrations in whole blood, plasma and serum in 65 samples obtained from 10 patients, with propofol concentrations in the range 0.5–7.5 μg ml^{-1}. Propofol concentrations in whole

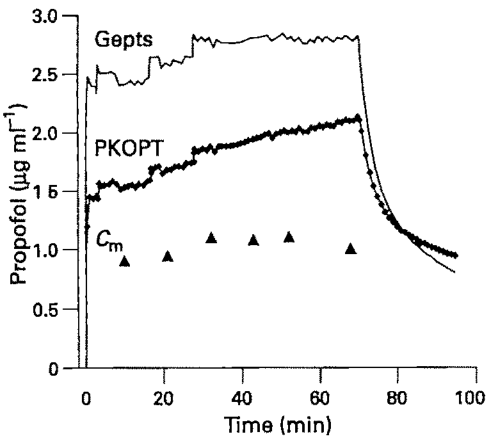

Figure 6 Predicted and measured serum propofol concentrations in one anxious patient receiving a target-controlled propofol infusion using a pump programmed with the pharmacokinetic microconstants published by Gepts and colleagues[6] and time course of theoretical blood propofol concentrations after re-simulation using the optimized microconstants from the PKOPT program. C_m = measured serum propofol concentration.

blood were, on average, 0.3 μg ml^{-1} higher than in serum, and there were no significant differences between concentrations in plasma and serum. The authors concluded that the differences were not large enough to influence the concentrations achieved and the prediction errors.[15] It is possible that part of the observed difference between predicted and measured propofol concentration in our study can be attributed to the difference in blood propofol determination between our study and that of Gepts' (whole blood).

In both the anxious and non-anxious groups in our study, over prediction of the delivery system model (Gepts) diminished with time such that after approximately 60 min of infusion time the model tended rather to under predict the measured concentrations than vice versa. This observation suggests that, in the context of the present study, the use of the Gepts' model in the delivery system produced an inherent tendency to drift towards a deeper level of sedation despite the pump settings remaining constant. The reason for this is apparent from figure 6. This illustrates the results of a computer simulation of predicted propofol concentrations in one of the study 1 patients receiving propofol from the TCI system programmed with Gepts' kinetic set, but projected instead into the new model derived by the optimization program. It can be seen that the predicted propofol concentrations according to the new model are initially substantially lower than those predicted by the Gepts' model but progressively increase during the course of the infusion. The refined model derived by the optimization program successfully eliminated this problem and produced a stable time relationship between measured and predicted values.

Hepatic extraction of propofol is high and clearance is dependent on liver blood flow.[15] Propofol has been shown to decrease cardiac output in a dose-dependent manner in humans, which in turn may dynamically influence propofol kinetics by reducing the rate of distribution to peripheral tissues and thereby contributing to a reduction in hepatic blood flow. It is conceivable that the higher age of Gepts' patients, possibly combined with reduction in cardiac output or hepatic blood flow, or both, may have resulted in lower values for propofol clearance than were observed in our study. The substantial negative bias observed in our sedation study was predicted by Coetzee and colleagues[15] who proposed that the clearance of propofol is concentration dependent. Clearance and distribution of the drug were postulated to occur at a faster rate at lower concentrations. Thus a pharmacokinetic study performed at higher concentrations would produce slower kinetics than one performed at a lower concentration. The results of our study support the hypothesis that the pharmacokinetics of propofol are concentration dependent.

Skipsey and colleagues[16] reported in a study involving older patients undergoing orthopaedic procedures under regional anaesthesia that their patients were satisfactorily sedated at a mean blood propofol concentration of 1.05 [range 0.15–2.63] μg ml^{-1}. Our findings are in accordance with their statement that patients with a blood propofol concentration of approximately 1–1.5 μg ml^{-1} are sedated but respond to verbal stimulation. This appeared to be true both in anxious patients and non-anxious control subjects.

The main purpose of a TCI pump is to produce a stable blood concentration of the delivered drug which is as close as possible to that predicted by the delivery system algorithm. The pharmacokinetic performance of any TCI system is thus highly dependent on how well the applied pharmacokinetic data in the delivery program match the characteristics of the target population. Inter- and intra-patient variability, variable intraoperative haemodynamic states and changing surgical stimulus contribute to considerable variability in pump performance in clinical practice. In the context of conscious sedation, the appropriateness of the pharmacokinetic delivery system model is particularly important because the therapeutic range for sedation is much smaller than for general anaesthesia. Our study demonstrated that the 10–90 percentile range predicted target concentration selected for conscious sedation in anxious patients was 2.11–2.65 μg ml^{-1} whereas the corresponding range for general anaesthesia is 2–10 μg ml^{-1}.[17] Relatively small prediction errors result in over or under sedation.

One of the main objectives of this study was to derive a new set of pharmacokinetic constants which more accurately described the elimination of propofol in anxious patients undergoing conscious sedation. The optimized model produced significantly ($P<0.01$) improved pharmacokinetic performance compared with the original system using the pharmacokinetic microconstants derived by Gepts and colleagues[6] and this result could be confirmed in a prospective study. The new model also demonstrated improved time related performance producing accurate and stable concentrations of propofol over a time period of up to 2 h.

Positive pressure ventilation with the laryngeal mask airway in non-paralysed patients: comparison of sevoflurane and propofol maintenance techniques

C. KELLER, H. J. SPARR AND J. R. BRIMACOMBE

Summary

We have compared anaesthetic maintenance and emergence characteristics of propofol and sevoflurane with the laryngeal mask airway (LMA) at commonly used doses in 185 ASA I–II patients, in a randomized, prospective study. Anaesthesia was induced with propofol 2.5–3.5 mg kg^{-1} and fentanyl 1–3 μg kg^{-1}. Neuromuscular blocking agents were not used. All patients underwent positive pressure ventilation (PPV) with tidal volumes of 6–8 ml kg^{-1} to maintain normal end-tidal carbon dioxide concentration. Anaesthesia was maintained with 66% nitrous oxide in oxygen and infusion of propofol 6 or 8 mg kg^{-1} h^{-1}, or 1% or 1.5% end-tidal sevoflurane. There were no failed insertion attempts and adequate ventilation was achieved in all patients. During emergence, there was a greater incidence of excitatory phenomena with 1% and 1.5% sevoflurane (95% confidence intervals (CI) 4–19%) compared with propofol (95% CI 0–4%). Sevoflurane 1.0% (95% CI 37–71%) was associated with the greatest overall incidence of respiratory and haemodynamic problems. This was significantly higher compared with propofol 6 mg kg^{-1} h^{-1} (95% CI 19–36%). Shorter times to LMA removal were observed with 1% and 1.5% sevoflurane compared with propofol ($P<0.0002$). Postoperative problems did not differ between groups. We conclude that propofol 6–8 mg kg^{-1} h^{-1} and 1.5% sevoflurane were suitable for maintenance of anaesthesia for musculoskeletal surgery in non-paralysed ASA I–II patients undergoing PPV with the LMA. Emergence was more rapid with sevoflurane, but was associated with more excitatory phenomena. (*Br. J. Anaesth.* 1998; **80**: 332–336)

Keywords: equipment, masks anaesthesia; ventilation, positive pressure; anaesthetics volatile, sevoflurane; anaesthetics i.v., propofol

Propofol is becoming increasingly popular for maintenance of anaesthesia, particularly for ambulatory surgery,[1] and sevoflurane is an acceptable alternative.[2-4] Both agents allow rapid changes in anaesthetic depth, a favourable emergence profile and minimal postoperative morbidity. Studies have compared propofol with sevoflurane anaesthesia in paralysed patients with the trachea intubated, and shown them to be similar in terms of cardiorespiratory effects, emergence times and adverse events.[2-4]

The laryngeal mask airway (LMA) has gained widespread acceptance as a general purpose airway, with usage rates of up to 30%.[5] Large scale studies (total 18 410 patients) suggest it is safe and effective for spontaneous ventilation (8139 patients) and positive pressure ventilation (10 271 patients).[5-7] The LMA offers several advantages over the tracheal tube, including improved haemodynamic stability, reduced anaesthetic requirements for airway tolerance, lower frequency of coughing, improved oxygen saturation during emergence and less sore throat,[8] and does not require neuromuscular block. Although both propofol[9] and sevoflurane[10] have been used for maintenance of anaesthesia with the LMA, there have been no comparative studies evaluating their clinical efficacy.

In this randomized study, we have compared maintenance and emergence characteristics of sevoflurane–nitrous oxide with propofol–nitrous oxide anaesthesia at commonly used doses in non-paralysed patients undergoing ventilation with the LMA.

Patients and methods

This study was approved by the Research and Ethics Committees of the University Hospital of Innsbruck and written informed consent was obtained from all patients. We studied 185 consecutive patients undergoing musculoskeletal surgery expected to last more than 30 min in the supine position, allocated randomly to one of four treatment groups. In groups I and II anaesthesia was maintained with 66% nitrous oxide in oxygen and infusion of propofol 6 or 8 mg kg^{-1} h^{-1}, respectively. In groups III and IV anaesthesia was maintained with 66% nitrous oxide in oxygen and either 1% or 1.5% end-tidal sevoflurane, respectively. Sample size was based on the need to show a 20% difference in orientation time between groups, with a type I error of 0.05 and a power of 0.8.

Patients were excluded if they were less than 19 or more than 65 yr of age, ASA III–V, had a history of malignant hyperthermia, respiratory tract pathology, a sore throat within 10 days, known difficult airway,

body mass index greater than 30 kg m^{-2} or were at risk of regurgitation/aspiration (previous upper gastrointestinal tract surgery, known or symptomatic hiatus hernia, oesophageal reflux, peptic ulceration or not fasted).

Patients were allocated randomly to treatment groups by opening sealed envelopes, 1–2 h before operation. Anaesthesia was standardized. Premedication comprised midazolam 7.5 mg orally approximately 1 h before induction. Monitoring was started before induction of anaesthesia and included ECG, pulse oximetry, capnography and non-invasive arterial pressure. Oxygen was given by face mask and then fentanyl 1–3 μg kg^{-1} was given followed 1 min later by propofol 2.5–3.5 mg kg^{-1} over 30 s. Immediately before insertion, the LMA was lubricated with saline. No attempt was made to ventilate the patient's lungs via a face mask or to instrument the airway with suction catheters at any time during anaesthesia. The LMA was inserted 30 s after completion of the bolus dose of propofol using the standard recommended insertion technique,[11] with the cuff deflated and the rim facing posteriorly when the eyelash reflex was lost and the jaw relaxed. A size 3 LMA was used for patients weighing 30–60 kg and a size 4 for patients more than 60 kg (size 5 LMA was unavailable during the study). Additional bolus doses of propofol 0.5 mg kg^{-1} were given as required until an adequate level of anaesthesia was achieved for placement. All LMA were inserted by a single experienced user (C. K.) (more than 800 previous placements). The cuff was initially inflated with 20 ml of air in the size 3 and 30 ml in the size 4. Successful placement was judged by chest wall movement and capnography during manually assisted ventilation. After successful placement, the LMA was fixed in place in the midline with the tube following its natural caudal curve using adhesive tape.[11] A wad of gauze swabs rolled into a cylindrical shape was placed alongside the LMA to function as a bite block.[11] Cuff pressures were monitored throughout the procedure using a calibrated aneroid manometer (Mallinckrodt Medical, Athlone, Ireland) which was attached to the pilot balloon. Cuff pressures were maintained at less than 60 cm H_2O by intermittently withdrawing gas from the cuff. Patients underwent positive pressure ventilation (PPV) with tidal volumes of 6–8 ml kg^{-1} and peak airway pressures were limited to 15 cm H_2O. Ventilatory frequency was adjusted to maintain end-tidal carbon dioxide in the normal range (4.4–5.3 kPa).

Anaesthesia was maintained with 66% nitrous oxide in oxygen and propofol 6 or 8 mg kg^{-1} h^{-1}, or 1.0% or 1.5% end-tidal sevoflurane. Airway gases were sampled from the proximal end of the LMA. A circle anaesthetic breathing system was used and there was no active humidification in the anaesthesia system. Fresh gas flows were 2 litre min^{-1} of oxygen and 4 litre min^{-1} of nitrous oxide. Depth of anaesthesia was assessed by observing ventilatory frequency, patient movement, heart rate and arterial pressure and, if considered inadequate, fentanyl 1 μg kg^{-1} was given. If coughing, retching or laryngospasm occurred, propofol 0.5 mg kg^{-1} was given. The maintenance dose of propofol or sevoflurane was continued until completion of surgery. Emergence took place in the operating room in the supine position with the patient undisturbed and breathing 100% oxygen. LMA removal time was determined by asking the patient in a normal tone of voice to open his or her eyes and mouth. This was repeated every 15–30 s until both appropriate responses were obtained. The LMA and bite block were removed simultaneously and the time recorded. Orientation time was determined by asking the patient in a normal tone of voice to state his or her name and date of birth. This was repeated every 15–30 s until a correct response was obtained and the time recorded.

Patient data, including sex, age, weight, smoking history and duration of surgery were recorded for each patient. In addition to the standard anaesthetic record, mean arterial pressure (MAP) and heart rate (HR) were recorded before induction, every minute from induction to incision, every 5 min after incision, and every minute after anaesthesia was discontinued until the LMA was removed. Problems during induction and surgery were documented by the anaesthetist (C. K.) not blinded to the type of anaesthetic. Problems during emergence and in the postoperative period were recorded by an anaesthetist (H. S.) blinded to the type of anaesthetic. Problems were classified as respiratory, haemodynamic or excitatory phenomena. Respiratory problems included failed insertion attempt (failed placement within 20 s), failed ventilation (failure to maintain Pa_{CO_2} within the normal range or Sp_{O_2} <95% with FI_{O_2}>33%), coughing, retching, hiccup, laryngospasm (a sudden increase in peak airway pressure greater than 25 cm H_2O), bronchospasm, regurgitation, aspiration, gastric insufflation (air heard entering the stomach on auscultation over the epigastrium), increased salivation, biting and any other untoward airway event. Haemodynamic problems included hypertension/hypotension, tachycardia/bradycardia and other arrhythmias. Hypertension or hypotension was defined as MAP±20% of preinduction baseline values, respectively. Tachycardia or bradycardia was defined as heart rate greater that 100 beat min^{-1} or less than 60 beat min^{-1}, respectively. Excitatory phenomena included inco-ordinate movement, shivering and straining. Successful induction, maintenance and emergence were defined as the absence of any respiratory or cardiovascular problems during that time. Anaesthesia was divided into three phases: induction (start of anaesthesia until successful placement of the LMA); maintenance (successful placement of the LMA until anaesthesia discontinued) and emergence (anaesthesia discontinued until patient orientated). Time intervals recorded included anaesthesia time (start of anaesthesia until anaesthesia discontinued), LMA removal time (anaesthesia discontinued until LMA removed) and orientation time (anaesthesia discontinued until patient orientated).

Each patient underwent a structured interview (H. S.) 18–24 h after surgery during which they were asked about postoperative hoarseness (yes/no), nausea (yes/no) and vomiting (yes/no). Sore throat was graded by the patient as none (no sore throat at any time since the operation), mild (sore throat disappeared within 6 h), moderate (sore throat disappeared within 12 h) and severe (sore throat lasted 12 h or more).

Data were analysed with the Student's *t* test and chi-square test using the software package SPSS

Results

There were no significant differences between the four groups in age, weight, height, body mass index, ASA status, sex distribution, smoking history, type of surgical procedure, anaesthesia time, administration of adjunctive drugs and induction doses of fentanyl and propofol (table 1).

Problems occurring during the three phases of anaesthesia are given in table 2. There were no failed insertion attempts and adequate ventilation was achieved in all patients. The lowest oxygen saturation recorded during the study was 95%. There were no episodes of gastric distension, regurgitation, aspiration or bronchospasm. The incidence of problems at induction was similar in all groups. During maintenance, the incidence of laryngospasm and requirements for additional propofol were greater with 1% sevoflurane (95% confidence intervals (CI) 2–23%) compared with 1.5% sevoflurane (95% CI 0–8%) or the propofol groups (95% CI 0–7%). During emergence, there was a greater incidence of excitatory phenomena with 1% and 1.5% sevoflurane (95% CI 4–9%) compared with propofol (95% CI 0–4%).

HR (fig. 1) and MAP (fig. 2) for each group were similar during induction and maintenance of anaesthesia. There was no haemodynamic stress response to placement of the LMA. During emergence, HR was greater with sevoflurane at 3–7 min after discontinuation of anaesthesia ($P<0.05$). MAP was similar.

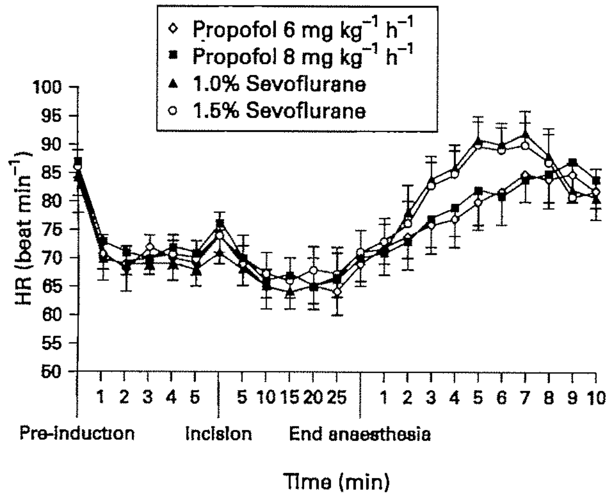

Figure 1 Heart rate (HR) before induction of anaesthesia, at the indicated times after induction, at skin incision, at the indicated times after skin incision, at the end of administration of anaesthesia and at the indicated times after anaesthesia in the four treatment groups (mean (SD)). HR was significantly greater with sevoflurane at 3–7 min after discontinuation of anaesthesia.

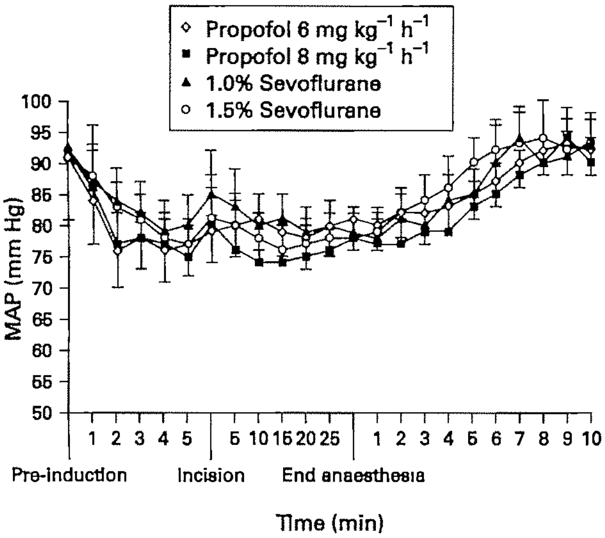

Figure 2 Mean arterial pressure (MAP) before induction of anaesthesia, at the indicated times after induction, at skin incision, at the indicated times after skin incision, at the end of administration of anaesthesia and at the indicated times after anaesthesia in the four treatment groups (mean (SD)). There were no significant differences between groups.

The total number of patients with respiratory and haemodynamic problems during each phase of anaesthesia is given in table 3. Sevoflurane 1.0% (95% CI 37–71%) was associated with the greatest overall incidence of respiratory and haemodynamic problems. This was significantly higher compared with propofol 6 mg kg^{-1} h^{-1} (95% CI 19–36%), but there were no other significant differences between groups. Significantly shorter times to LMA removal and orientation were observed with 1% and 1.5% sevoflurane compared with propofol 6 and 8 mg kg^{-1} h^{-1} ($P<0.0002$). Removal and orientation times were similar for 1% sevoflurane compared with 1.5% sevoflurane, and similar for propofol 6 and 8 mg kg^{-1} h^{-1}. Postoperative problems did not differ between groups. The incidence of sore throat was 2.7% and hoarseness 0%. The number of patients who received postoperative analgesia was similar between groups.

Discussion

Our data suggest that maintenance of anaesthesia with propofol 6–8 mg kg^{-1} h^{-1} or 1.5% sevoflurane in nitrous oxide provides satisfactory anaesthetic conditions in non-paralysed patients undergoing ventilation with an LMA. Sevoflurane 1.0% provided less satisfactory conditions and this was probably related to inadequate depth of anaesthesia. The overall incidence of problem-free maintenance and emergence was similar to that reported in paralysed patients whose tracheas were intubated,[3] but randomized controlled studies are required to determine if either technique offers an advantage.

During induction and maintenance of anaesthesia, haemodynamic variables were similar. This contrasts with the results of Fredman and colleagues who showed slower heart rates in the immediate post-induction period in paralysed patients whose tracheas were intubated.[2] The reason for this difference is not clear. During emergence, heart rate was greater with sevoflurane. MAP was similar in all groups during emergence. The high incidence of bradycardia in all groups may reflect the lack of cardiovascular stimulation resulting from the LMA.

The efficacy of the LMA technique for PPV is already established, but most controlled studies involve paralysed patients.[7] [12–15] Our data suggest that the technique is also suitable for non-paralysed patients. It is interesting that, despite cuff pressure limitation to 60 cm H_2O, in all patients ventilation was adequate using tidal volumes of 6–8 ml kg^{-1} and peak airway pressures of 15 cm H_2O. This may be related to the relatively low body mass index of the study population (BMI <30 kg m^{-2}) and accurate placement of the device. Dyer, Llewellyn and James have shown the LMA to be an effective device for PPV using total i.v. anaesthesia with propofol and easier to manage than the tracheal tube in the absence of neuromuscular blockers.[9]

The times required for LMA removal and orientation were shorter with sevoflurane. These times

Table 3 Incidence of respiratory and haemodynamic problems during each phase of anaesthesia (number (%))

	Propofol		Sevoflurane	
	Group I 6 mg kg^{-1} h^{-1}	Group II 8 mg kg^{-1} h^{-1}	Group III 1.0%	Group IV 1.5%
n	47	48	45	45
Induction	3 (6%)	3 (6%)	2 (4%)	2 (4%)
Maintenance	10 (21%)	12 (25%)	16 (36%)	11 (24%)
Emergence	5 (11%)	8 (17%)	13 (29%)	11 (24%)
Total	14 (30%)	18 (37%)	25 (56%)	19 (42%)

were similar to those reported for sevoflurane and propofol in paralysed patients whose tracheas were intubated.[2 3] The highest incidence of nausea (7%) and vomiting (2%) was in the 1.5% sevoflurane group, but this was not significantly different from the other groups. The incidence of nausea and vomiting was 2–10 times less than previously reported for paralysed patients whose tracheas were intubated[5] and may reflect different methods of data collection, different types of surgery or antiemetic therapy. It would seem unlikely that this was related to the LMA as previous studies have reported a similar incidence of postoperative nausea and vomiting when comparing the LMA with the tracheal tube.[16 17] No routine intraoperative antiemetic was given in our study and there was no case of gastric insufflation.

The incidence of sore throat with the LMA is approximately 10%, but varies between 0 and 50%,[18–23] and the incidence of hoarseness is approximately 4%.[21–24] The incidence of sore throat and hoarseness in our study was low (2.7% and 0%, respectively). This probably reflects the high first time placement rate, use of standard insertion technique and adoption of low intra-cuff pressures. All LMA were inserted by an experienced user with more than 800 previous placements. It has been shown that there are short-term (>75 uses)[25] and long-term (>750 uses)[6] learning curves with the LMA. Burgard, Mollhoff and Prien demonstrated that reducing cuff pressure to the minimum required for an adequate seal produced a reduction in sore throat from 8 to 0%.[22] The 13% incidence of biting during emergence highlights the importance of using a bite block with the LMA.

We conclude that propofol 6–8 mg kg^{-1} h^{-1} and 1.5% end-tidal sevoflurane were suitable for maintenance of anaesthesia for musculoskeletal surgery in non-paralysed ASA I–II patients undergoing PPV with the LMA. Emergence was more rapid with sevoflurane, but was associated with more excitatory phenomena and tachycardia.

Catheter deadspace: a source of error during tonometry

P. J. G. M. STEVERINK, J. J. KOLKMAN, A. B. J. GROENEVELD AND J. W DE VRIES

Summary

Tonometry of $P\text{co}_2$ is a promising method for assessing the oxygen supply to demand ratio of the gastrointestinal mucosa in critically ill patients. A balloon-tipped tonometer is introduced into the stomach or sigmoid colon, and saline is instilled into the balloon. After a time to allow partial equilibration with intraluminal $P\text{co}_2$, saline is aspirated and $P\text{co}_2$ is measured. Intermittent instillation and aspiration of saline allows serial $P\text{co}_2$ measurements, provided correction factors are used to calculate the $P\text{co}_2$ value expected at full equilibration from the $P\text{o}_2$ values measured after short dwell times. The technique is not yet widely applied, partly because of methodological controversies. We evaluated the role of the catheter deadspace as a source of error during $P\text{co}_2$ tonometry. The increase in $P\text{co}_2$ in sigmoid-type tonometers with a normal length (normal tonometer (NT)) and in those with a 50% increase in length and thus deadspace (extended tonometer (ET)), in a saline bath at a $P\text{co}_2$ of 4.8 kPa was assessed. Saline dwell times were 10, 20, 30, 45, 60 and 90 min and the time-dependent $P\text{co}_2$ increase was determined at deadspace $P\text{co}_2$ values of approximately 4.0 and 8.0 kPa following contamination of the catheter deadspace after immersion in saline baths at $P\text{co}_2$ values of 4.8 and 9.6 kPa, respectively, before each measurement cycle. In another experiment, the tonometer was rinsed between measurement cycles to remove deadspace saline containing carbon dioxide and to obviate contamination of instilled saline. $P\text{co}_2$ was measured in a blood-gas analyser, taking into account measurement bias in saline. Failure to remove deadspace saline between measurement cycles resulted in an overestimation of 10% and 6% for the NT and 16% and 10% for the ET, at saline dwell times of 10 and 20 min, respectively, at a deadspace $P\text{co}_2$ of approximately 4.0 kPa. At a deadspace $P\text{co}_2$ of approximately 8.0 kPa, $P\text{co}_2$ was overestimated by 17%, 11% and 5% for the NT and 31%, 20% and 11% for the ET, at dwell times of 10, 20 and 30 min, respectively. Rinsing the NT/ET resulted in accurate assessment of $P\text{co}_2$ at all dwell times, but the dwell time-dependent increase in $P\text{co}_2$ was slightly slower in the ET, particularly at 10 min, after a sink effect of the increased deadspace. Hence, a previously unrecognized deadspace effect caused error during $P\text{co}_2$ tonometry, particularly with short dwell times. This potentially large error can be avoided by rinsing the tonometer before each measurement cycle, allowing accurate $P\text{co}_2$ tonometry even at 10-min saline dwell times, provided that correction factors are used that are specific for catheter size. These findings may help to widen the clinical applicability of tonometry. (*Br. J. Anaesth.* 1998; **80**: 337–341)

Keywords: carbon dioxide, partial pressure; airway, deadspace; monitoring, tonometry

The tonometry of intraluminal $P\text{co}_2$ in the gastrointestinal tract and calculation of intramucosal pH may be useful in assessing the prognosis and guiding treatment of critically ill patients.[1–8] During tonometry, saline instilled into the tonometer balloon is allowed to equilibrate with intraluminal $P\text{co}_2$. After a certain dwell time, saline is aspirated and $P\text{co}_2$ is measured in a conventional blood-gas analyser.[9 10]

There are various problems with the methods for this technique[8] that may lead to errors.[9–11] First, carbon dioxide may be lost from the aspirate during transport and second, most blood-gas analysers underestimate $P\text{co}_2$ measured in saline.[12–16] Finally, a major disadvantage of tonometry is its relative slowness, as complete equilibration between balloon and intraluminal $P\text{co}_2$ may require 60 min. As this is impractical for clinical purposes, correction factors have been provided to calculate steady state $P\text{co}_2$ when short dwell times are applied. Even with the use of these factors, dwell times of less than 30 min are discouraged as they are believed to yield inaccurate results.[17]

A hitherto overlooked source of error is the carbon dioxide impermeable deadspace of the catheter, which may have two consequences. First, with each measurement, saline that contains carbon dioxide is retained in the deadspace after aspiration and then flushed into the balloon at the next saline instillation, thereby increasing balloon $P\text{co}_2$ before each measurement cycle. This may lead to saline $P\text{co}_2$ overestimation, particularly at short dwell times. Second, the deadspace may serve as a sink for $P\text{co}_2$

increase in the saline of the balloon, so that the correction factors may depend on the size and thus the deadspace volume of the catheter used. Conversely, this may help to explain the differences in correction factors between gastric- and sigmoid-type tonometers of different lengths.[17] Successful elimination of sources of error may widen the clinical applicability of manual tonometry in centres where the recently introduced, semi-continuous and automated air tonometry, a technique of proven reliability, is not available.[18 19]

Therefore, we studied *in vitro* the effect of the catheter deadspace on $P\text{CO}_2$ tonometry. $P\text{CO}_2$ was measured after various saline dwell times using a normal tonometer and an extended tonometer with an increased deadspace, both with and without rinsing the carbon dioxide containing deadspace of the tonometer before each measurement cycle.

Materials and methods

A steady state $P\text{CO}_2$ in a 3-litre, temperature-controlled (mean 37.0 (SD 0.2) °C) saline bath was achieved by bubbling carbon dioxide calibration gases (4.98% and 9.98% in nitrogen, both with an accuracy of 1%; NTG, Tilburg, The Netherlands) at a flow rate of 5 litre min^{-1}. Bath $P\text{CO}_2$ was assumed to have reached steady state when five consecutive measurements at 5-min intervals differed by less than 5%.

Bias and precision of $P\text{CO}_2$ measurements in saline with the blood-gas analyser (ABL 505, Radiometer, Copenhagen, Denmark) were derived from comparison of the measured bath $P\text{CO}_2$ at steady state with the expected bath $P\text{CO}_2$, calculated from the carbon dioxide content of the calibration gas, bath temperature and barometric pressure (Pbar), according to $P\text{CO}_2=(P\text{bar}-47)\times100\times\%$ carbon dioxide content. The measured bath $P\text{CO}_2$ at steady state underestimated the expected $P\text{CO}_2$: mean 4.5 (SD 0.2) kPa (n=32) *vs* 4.8 kPa ($P<0.0001$), and 8.8 (0.2) *vs* 9.6 kPa ($P<0.0001$), respectively. The bias of the $P\text{CO}_2$ measurements, defined as the mean percentage difference between measured and expected $P\text{CO}_2$, was thus −6.8%. Precision, the SD of bias, was 3.0%. Bias and precision were independent of bath $P\text{CO}_2$. Underestimation of $P\text{CO}_2$ measured in saline with the type of blood-gas analyser used is in agreement with the literature.[15–16] Thus all $P\text{CO}_2$ measurements in saline were multiplied by a factor of 1.07 (=100/93.2).

For our *in vitro* study we used TRIP Sigmoid tonometers (Tonometrics, Inc., Bethesda, MD, USA), as applied previously for gastric tonometry in healthy volunteers.[20] We did not compare sigmoid (length 202 cm) with gastric (length 150 cm) tonometers, which have different deadspaces, because the catheters not only differ in length but also in external diameter, at similar balloon properties. The correction factors for the increase in $P\text{CO}_2$ in the tonometer types differ, as stated by the manufacturer,[17] and this may indicate that the increase in $P\text{CO}_2$ as a function of time may be slower in the sigmoid-type tonometer, but the reason is not given. To evaluate the effect of deadspace on the increase in $P\text{CO}_2$ in the balloon saline as a function of time, we decided to use tonometers of the same type with different lengths and thus deadspace volumes, and the manufacturer kindly supplied sigmoid-type tonometers that were extended to 300 cm. All tonometers had identical stopcocks, balloons and tube material. The deadspace was assessed with a micro-syringe, after cutting the tube at balloon entry. The deadspace volume was 1.07±0.02 ml in the normal sigmoid-type tonometer (normal tonometer (NT), n=10) and 1.71±0.03 ml in the extended sigmoid-type tonometer (extended tonometer (ET), n=10). Carbon dioxide permeability of the tube was also assessed (n=6). After cutting off the balloon and stopcock, the tubes were filled with saline, sealed and placed in a saline bath with a $P\text{CO}_2$ value of 9.6 kPa for 24 h at 37°C. The tube was then opened, saline aspirated immediately and $P\text{CO}_2$ measured in a blood-gas analyser. $P\text{CO}_2$ increased by only 0.5±0.2 kPa at 24 h.

The time-dependent increase in $P\text{CO}_2$ in the balloons of the tonometers (n=6 NT, n=12 ET) at saline dwell times of 10, 20, 30, 45, 60 and 90 min was determined in two experiments for each type of tonometer. Each measurement cycle consisted of introducing 2.5 ml of saline into the tonometer balloon, a certain dwell time for (partial) equilibration, and aspiration. The first 1.1 ml aspirated in the NT and 1.7 ml in the ET was considered to represent the deadspace and was discarded. The final aspirate was introduced into the blood-gas analyser for $P\text{CO}_2$ measurements. In experiment I, the effect of carbon dioxide contamination of the deadspace saline on the time-dependent increase in $P\text{CO}_2$ in a bath of $P\text{CO}_2$ 4.8 kPa was evaluated. Before each measurement cycle, the following were performed: (1) rinsing of the tonometer with fresh saline; (2) filling of the tonometer with saline 2.5 ml and immersion in a saline bath at a $P\text{CO}_2$ of 4.8 kPa or 9.6 kPa for 30 min; (3) aspiration and disposal of saline 2.5 ml, thereby retaining the deadspace volume with an estimated $P\text{CO}_2$ of approximately 4.0 kPa and 8.0 kPa, respectively; and (4) placing the tonometer in a saline bath at a $P\text{CO}_2$ of 4.8 kPa for a measurement cycle. In experiment II, the increase in $P\text{CO}_2$ was determined in saline baths at $P\text{CO}_2$ values of 4.8 and 9.6 kPa, and all residual carbon dioxide in the deadspace saline was removed by rinsing the tonometer three times with 2.5 ml of fresh saline, before each measurement cycle.

STATISTICAL ANALYSIS

For experiment II, the increase in $P\text{CO}_2$ in the tonometer balloon, in terms of $P\text{CO}_2(\text{ss})$ (steady state $P\text{CO}_2$) and $T½$ (half-time), was assessed by non-linear regression analysis according to: $P\text{CO}_2(t)=((P\text{CO}_2(\text{ss})\times t)/(T½+t)$, where $P\text{CO}_2(t)=P\text{CO}_2$ at t (min) dwell time. Mean data were used to plot the regression curve. The characteristics of the increase in $P\text{CO}_2$ in the NT and ET were compared using Student's t test. Correction factors for calculation of $P\text{CO}_2(\text{ss})$ from $P\text{CO}_2(t)$ at each dwell time were calculated for each tonometer type. To judge the accuracy of $P\text{CO}_2(\text{ss})$, estimated using the correction factors at each dwell time in predicting bath $P\text{CO}_2$, we calculated the bias and precision for $P\text{CO}_2(\text{ss})$ for each dwell time. The bias represents the percentage difference in $P\text{CO}_2(\text{ss})$ and bath $P\text{CO}_2$ and precision is the SD

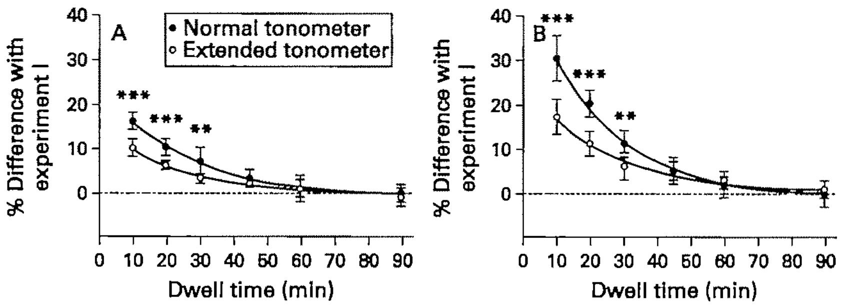

Figure 1 Effect of carbon dioxide contamination of deadspace on the increase in Pco$_2$. A: Immersion for 30 min in a bath at a Pco$_2$ value of 4.8 kPa (deadspace Pco$_2$ approximately 4.0 kPa) before each measurement cycle of Pco$_2$ increase. B: Immersion for 30 min in a bath at a Pco$_2$ value of 9.6 kPa (deadspace Pco$_2$ approximately 8.0 kPa) before each measurement cycle of Pco$_2$ increase in a bath at Pco$_2$ 4.8 kPa. Mean (SD) percentage difference in Pco$_2$ at corresponding dwell times in figure 2 and non-linear regression curve for means for the normal tonometer and extended tonometer. **$P<0.01$; ***$P<0.001$ between tonometers.

of bias. For experiment I, Pco$_2$ after each dwell time was expressed as the percentage difference in Pco$_2$ measured at corresponding dwell times in experiment II. For graphical presentation, non-linear regression curves were calculated using mean values and a one-phase exponential decay. Data are expressed as mean (SD). $P<0.05$ was considered statistically significant.

Results

EXPERIMENT I

At a deadspace Pco$_2$ of approximately 4.0 kPa (bath Pco$_2$ 4.8 kPa), the increase in Pco$_2$ was different from that in experiment II, as Pco$_2$ measured at short dwell times was increased, especially in the ET (fig. 1A). With the NT, Pco$_2$ was significantly overestimated at dwell times of 10 and 20 min by mean 10% and 6%, respectively. With the ET, Pco$_2$ overestimation after 10, 20 and 30 min was 16%, 10% and 5%, respectively. At a deadspace Pco$_2$ of approximately 8.0 kPa (bath Pco$_2$ 9.6 kPa), overestimation of Pco$_2$ at short dwell times was even greater and more pronounced with the ET (fig. 1B). In the NT, mean Pco$_2$ overestimation after 10, 20 and 30 min was 17%, 11% and 5%, respectively. In the ET, Pco$_2$ overestimation at 10, 20, 30 and 45 min was 31%, 20%, 11% and 5%, respectively.

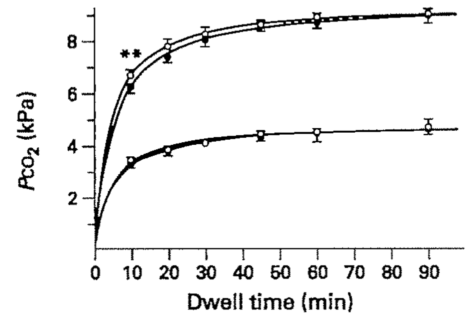

Figure 2 Increase in Pco$_2$ as a function of saline dwell time, in the normal and extended tonometer balloons in a saline bath at a Pco$_2$ value of 4.8 kPa (lower two curves) and 9.6 kPa (upper curves). Mean (SD) regression curve for means. **$P<0.01$ between tonometers.

Table 1 Mean bias and precision of Pco$_2$ tonometry for each saline dwell time, at bath Pco$_2$ values of 4.8 and 9.6 kPa. For measurement of bias and precision, the means of measurements at bath Pco$_2$ values of 4.8 and 9.6 kPa in experiment II were used. Bias is the percentage difference between bath Pco$_2$ and calculated Pco$_2$ (ss), Pco$_2$ (ss)=Pco$_2$ (t)×correction factor (t); precision is the SD of bias

Dwell time	Normal tonometer		Extended tonometer	
(t) (min)	Bias (%)	Precision (%)	Bias (%)	Precision (%)
10	−0.1	1.9	0.1	4.0
20	0.0	3.0	0.1	3.8
30	0.0	2.1	0.1	2.2
45	−0.1	2.1	0.1	2.5
60	0.0	1.5	0.1	3.0
90	0.0	3.0	0.1	2.7

EXPERIMENT II

The increase in Pco$_2$ in the tonometer balloon was described adequately by a non-linear regression model (fig. 2). The increase in Pco$_2$ in the NT was slightly faster than that in the ET, with an estimated T½ of 4.4 (0.5) and 5.3 (0.6) min, respectively ($P<0.001$). Hence, the 10-min Pco$_2$ value was significantly greater in the NT than in the ET at a bath Pco$_2$ of 9.6 kPa and the 10-min correction factors for estimation of Pco$_2$(ss) from Pco$_2$(t) differed between catheter types (1.40 (0.02) and 1.48 (0.04) for both bath Pco$_2$ values together, and for the NT and ET, respectively ($P<0.001$)). Pco$_2$(ss) in the NT and ET calculated from the non-linear regression equations did not differ from the bath Pco$_2$: Pco$_2$(ss) was 4.8 (0.1) and 4.9 (0.1) kPa at a bath Pco$_2$ of 4.8 kPa, and 9.5 (0.1) and 9.6 (0.1) kPa at a bath Pco$_2$ of 9.6 kPa for the NT and ET, respectively (ns). Bias and precision for Pco$_2$(ss) estimates, calculated from Pco$_2$(t) and correction factors for the NT and ET, were independent of saline dwell times (table 1). The pooled bias was 0.0 (0.1) % and precision was 2.7 (0.7)%, indicating accurate and reproducible Pco$_2$(ss) estimation.

Discussion

This study has indicated that a previously overlooked deadspace effect caused errors in Pco$_2$ tonometry at dwell times of less than 30 min. If this error is prevented by removal of deadspace saline containing carbon dioxide before each dwell time, $P\text{co}_2$ measurements at 10- and 20-min dwell times are as accurate as those obtained at longer dwell times, provided that correction factors are used that are specific for catheter size.

The longer T½ using the ET in experiment II, with an almost 50% larger deadspace than the NT, was probably a result of the deadspace acting as a sink for the increase in $P\text{co}_2$ in the tonometer balloon. However, the effect is only detectable at short dwell times and is probably small, as a 50% increase in deadspace reduced $P\text{co}_2$ at the 10-min dwell time by only 5%. The sink effect can be explained by diffusion of carbon dioxide into the saline of the balloon and, subsequently, into the catheter lumen and deadspace, so that the correction factors would become dependent, for a given balloon volume, on the deadspace and thereby on the length and diameter of the tonometer. With a larger sized catheter, more carbon dioxide diffuses into the deadspace and subsequently the increase in $P\text{co}_2$ in the balloon is slower. The sink effect may thus explain how measured $P\text{co}_2$, even after rinsing, is dependent on the deadspace, particularly at short dwell times and high surrounding $P\text{co}_2$ values. Indeed, the carbon dioxide diffusion rate, which depends on the pressure gradient, would be greater and therefore more dependent on the sink effect at a high surrounding $P\text{co}_2$ and a low $P\text{co}_2$ in the saline of the deadspace, that is shortly after introduction of fresh saline and start of a new measurement sequence. Conversely, reliable $P\text{co}_2$ measurements would be independent of the (size of) deadspace acting as a sink, at dwell times exceeding 10 min (fig. 2). A sink effect that depends on the ratio between catheter length and balloon volume may partly explain the difference in correction factors for gastric- and sigmoid-type tonometers provided by the manufacturer. A reduction in catheter volume to reduce the sink effect would be impracticable, as this would reduce the working length of the tonometer, and increasing balloon volume would further slow the increase in $P\text{co}_2$ in the balloon.

The most apparent effect of the tonometer deadspace on $P\text{co}_2$ measurements relates to recharging of the balloon saline by carbon dioxide-enriched deadspace saline. Failure to remove this deadspace saline before each measurement cycle resulted in overestimation of $P\text{co}_2$, particularly with the ET (experiment I) at saline dwell times of less than 30 min. This effect can be calculated, knowing the ratio of deadspace *vs* balloon volume (0.44 for the NT and 0.68 for ET), diffusion rate into the tonometer balloon and surrounding $P\text{co}_2$, using the formula: measured $P\text{co}_2$=(ratio×(deadspace $P\text{co}_2$))+(% diffusion×(surrounding $P\text{co}_2$−balloon $P\text{co}_2$)). The calculated overestimate for a 10-min dwell time, at steady state surrounding $P\text{co}_2$, would be 13% for NT and 21% for ET, which is in close agreement with our results. Similarly, it can be calculated that dwell times >30 min eliminate the effect, as equilibration is almost complete by this time. Prolonged dwell times are therefore unaffected by deadspace errors. In most clinical situations, the interval between measurement cycles can vary considerably and therefore the deadspace $P\text{co}_2$ is unpredictable, as is the way it may influence subsequent $P\text{co}_2$ determinations. There are two practicable options to eliminate the deadspace effect. Dwell times >30 min are chosen or the tonometer is rinsed before each measurement cycle. The results of experiment II (table 1) indicate that even dwell times of 10 min result in an estimation of surrounding $P\text{co}_2$ with similar bias and precision to those obtained after longer dwell times if the tonometer is rinsed before each measurement cycle. This may widen the clinical applicability of manual tonometry by allowing short-term evaluation of therapeutic interventions.

In summary, our study indicated that saline dwell times of less than 30 min yielded reliable results during $P\text{co}_2$ tonometry provided that the tonometer was rinsed before each measurement cycle and correction factors were used that were specific for catheter size. Failure to recognize the deadspace as a source of error may have affected results in recent studies on the value of splanchnic tonometry.[6–8]

Bispectral index: comparison of two montages

J. D. Hall and G. G. Lockwood

Summary

We have compared fronto-central and bifrontal montages using a new EEG monitor, the Aspect A-1000. The monitor uses bispectral analysis to derive an index of anaesthetic depth, the bispectral index (BIS). We compared reliability, impedance and BIS for each montage. ECG electrodes placed in a bifrontal montage were more reliable than silver dome electrodes in a fronto-central montage and both types of electrodes had impedances in the clinically useful range. However, BIS values derived from each montage were found to differ in an unpredictable manner. The bifrontal montage is easy to apply and reliable but it is not comparable with a fronto-central montage. We conclude that the BIS may be useful for following trends in anaesthetic depth in individual cases but it is less helpful when making comparison between patients or as a single value. (*Br. J. Anaesth.* 1998; **80**: 342–344)

Keywords: monitoring, electroencephalography; anaesthesia, depth; equipment, EEG monitor

A non-invasive, simple to use measurement of anaesthetic depth would be of great value. The measurement should preferably be based on changes at the anaesthetic site of action, ideally would be independent of anaesthetic type, and be able to predict awareness and recovery from anaesthesia. Many attempts have been made to use electroencephalograph (EEG) derivatives such as spectral edge frequency (SEF) and power spectral analysis (PSA) to measure changes in depth of anaesthesia. A limitation of these methods is that they do not use all of the information available within the EEG signal. For example, PSA can only quantify power distribution as a function of frequency, ignoring phase information.[1] SEF and PSA are not universally successful measures of anaesthetic depth and neither are used routinely in the clinical setting.

More recently, the Aspect A-1000, a four-channel EEG monitor, has been introduced into clinical practice in an attempt to fulfil this role. It generates a single number, termed the bispectral index (BIS), which is a guide to the level of consciousness. Initial studies used a fronto-parietal[2] or fronto-central[3] montage (lead arrangements) which requires electrodes to be sited within the hairline. Such montages may be difficult to use in routine clinical practice and the supposedly more convenient bifrontal montage, with electrodes positioned on the skin of the forehead, has also been used.[4] We have compared the BIS generated from two montages to determine if it is montage-dependent. We have also compared the reliability and impedance of ECG electrodes (which may be used conveniently for the bifrontal montage) with silver dome electrodes which are needed for the fronto-central montage.

Patients and methods

After obtaining approval from the local Research Ethics Committee, we studied 15 patients undergoing routine anaesthesia and surgery. Electrodes were placed at Fp1, Fpz, Fp2, C3, C4 and mastoid. The bifrontal and mastoid electrode sites were degreased with isopropanol, abraded with Nuprep (DO Weaver and Co., USA) and paediatric silver–silver chloride self-adhesive ECG electrodes (NiKo Medical Products) applied. The scalp was abraded with Nuprep at C3 and C4 and silver dome electrodes applied using Ten 20 (DO Weaver) adhesive paste. BIS was computed by an Aspect A-1000 (software v2.51 Aspect Medical Systems, Framingham, MA, USA) from the Fp1–Fpz and Fp2–Fpz pairs and from Fp1–C3 and Fp2–C4 pairs simultaneously, using the mastoid as ground.

Data were collected by computer every 15 s from 15 patients undergoing a variety of surgical procedures. Anaesthesia was not standardized and was controlled without regard to the results produced by the EEG. Electrode impedances were recorded whenever an impedance check was requested during the case, commonly when resiting an electrode. The last impedance value only from such an episode was used in the analysis. The security of lead placement was investigated by comparing the number of cases in which the frontal ECG leads were secure throughout, to the number of cases in which the central silver dome leads were secure throughout, using Fisher's exact test. The impedances of the two electrode types were compared using the Mann–Whitney test. BIS values from the bifrontal montage and fronto-central montage were compared using scatter plots for each individual. Data from all patients were pooled and the two montages correlated. Data were processed using Excel v7.0 and Arcus Biomedical v6.8.

Results

A total of 30 h of data were collected. At least one frontal electrode needed resiting during four cases, and at least one central electrode needed resiting

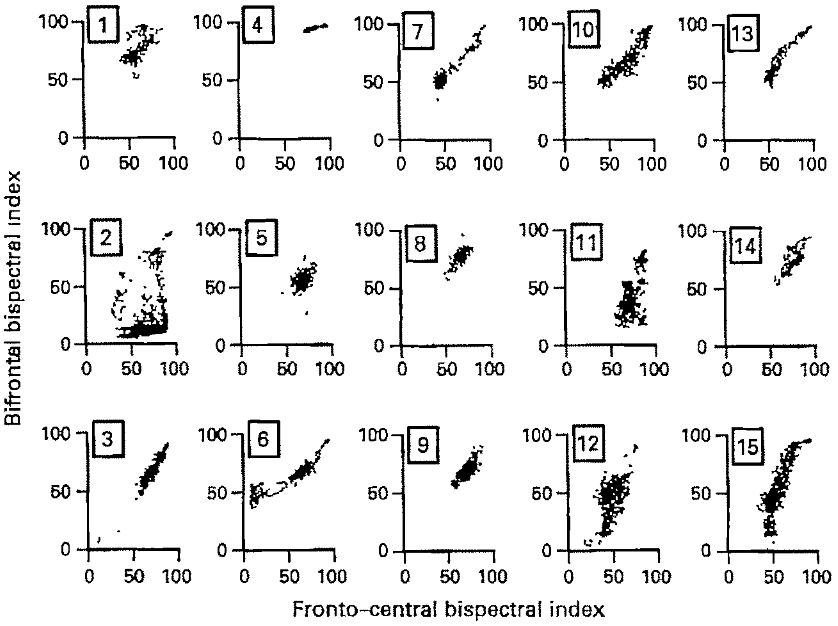

Figure 1 Fronto-central bispectral index plotted against bifrontal bispectral index for 15 patients during routine anaesthesia. Drugs administered included: methohexital (patient Nos 1, 3, 4, 5, 8, 9, 10, 12, 13 and 15), midazolam (patient Nos 2, 11, 12 and 15), fentanyl (patient Nos 2, 3, 5, 6, 7, 9, 10, 11, 12, 13, 14 and 15), morphine (patient Nos 3, 4, 6 and 8), pethidine (patient No. 1), halothane (patient Nos 2, 5 and 13), isoflurane (patient Nos 3, 4, 8, 9, 10 and 12), sevoflurane (patient Nos 1, 4 and 7), enflurane (patient Nos 6, 7 and 14), desflurane (patient No. 6) and propofol (patient Nos 1, 6, 11 and 14). The variable relationship between bispectral index derived from the two montages does not seem to be drug related, and in many individuals the difference in simultaneous bispectral index measurements is greater than the separation found between patients who moved in response to surgical stimulation and those who did not.

during 11 cases ($P < 0.02$). Median impedances were 2425 Ω (ECG electrodes) and 2700 Ω (dome electrodes). There was no difference in their distributions and values were within the clinically useful range.

Inspection of individual scatter plots of BIS from the two montages did not support the hypothesis that they were equivalent (see fig. 1). The agreement could not be improved by excluding BIS data pairs recorded during periods of poor signal quality or low total power. The pooled data revealed that the bifrontal BIS was, on average, 13 less than the fronto-central BIS and could be estimated as 0.68 (95% confidence intervals 0.65–0.71) of the fronto-central BIS.

Discussion

The EEG is a complex signal that can, through Fourier analysis, be broken down into several component frequencies. The analysis generates information on the frequency, power and phase of the signal and so facilitates interpretation. In order to use as much of the EEG signal as possible, a technique called bispectral analysis has been applied in the Aspect A-1000. This technique was developed in the 1960s by geophysicists to study retrospectively complex seismic waveforms.[5] The bispectrum is a measure of the level of phase coupling between different frequencies of the Fourier spectrum of a signal but it is difficult to interpret. Important information relating to anaesthetic effect may be contained within the phase relationships. Features of the EEG bispectrum which predicted response to surgical stimulus were defined using a stepwise regression.[6] These features were then combined using discriminant analysis into a multivariate index, with values from 0 to 100. This index is being refined and updated continually, although the details are not published, and it is known as the bispectral index (BIS). In summary, BIS is a number derived by the Aspect A-1000 from the bispectrum and other features of the EEG.

BIS has been investigated as an indicator of anaesthetic depth. One study showed that during thiopental–isoflurane anaesthesia with a fronto-parietal montage, BIS was significantly different between movers and non-movers.[6] In another study of isoflurane–alfentanil and propofol–alfentanil anaesthesia, BIS was significantly different between movers and non-movers in each anaesthetic group but could not differentiate between movers in the propofol group and non-movers in the isoflurane group.[7] BIS was also a better predictor of movement than end-expired isoflurane concentration.[7] These results suggest that BIS is dependent on the drug used in addition to depth of anaesthesia.

Regardless of its capability as a monitor of anaesthetic depth, we believe that it must be convenient to use if it is to become accepted clinically. We have not found the manufacturer's recommended electrodes (Zip-Prep, Aspect Medical Systems) to be useful within the hairline and in such positions we have had consistent success only with silver dome electrodes. Frontal electrodes are easier to apply and we have shown that they give a more reliable signal, which probably explains their adoption in more recent studies. It would be convenient if the BIS was independent of the choice of montage, but Kochs and co-workers found that EEG changes were dominant in frontal areas during isoflurane anaesthesia[8] and therefore it might be expected that different montages would give more or less sensitive indices of depth of anaesthesia.

Individual BIS data (fig. 1) showed differences between montages. Although a few cases showed excellent agreement between the two montages, in the majority the difference between the bifrontal and fronto-central BIS was too great and too unpredictable to enable them to be used interchangeably under clinical conditions. For example, when the fronto-central BIS is in the clinically important range of 60–70, 50% of bifrontal BIS measurements were outside the range 44–67 and 10% outside the range 11–77. We conclude that if comparisons between bispectral indices are to be made, it is important that the montages and anaesthetics used are the same. If bifrontal ECG electrodes are used to obtain a BIS value during anaesthesia, it is important not to act on the measured value on the basis of studies using fronto-central montages. The BIS may be useful for trends in individuals, but single values or comparison between patients are of little use.

Laryngoscopy and fibreoptic intubation in acromegalic patients

P. HAKALA, T. RANDELL AND H. VALLI

Summary

Acromegaly is recognized as a cause of difficulty in airway management and tracheal intubation. We evaluated prospectively the conditions for laryngoscopy and fibreoptic intubation in 15 acromegalic patients. Each patient served as his or her own control. Ventilation of the lungs with a face mask was successful in all patients. In five of 15 patients the vocal cords could not be seen using the Macintosh laryngoscope with a size 5 blade. Difficult laryngoscopy was associated significantly with the number of attempts required to see the vocal cords with the fibrescope ($P<0.01$, Spearman rank correlation). The larynx could not be seen with both techniques in one patient, and the trachea was intubated blindly with the help of an introducer. Our results showed that fibreoptic intubation may prove difficult or fail in acromegalic patients. Difficulties in seeing the vocal cords with a fibrescope were present most often in patients who also had probable intubation difficulties with a rigid laryngoscope. (*Br. J. Anaesth.* 1998; **80**: 345–347)

Keywords: complications, acromegaly; larynx, laryngoscopy fibreoptic; intubation tracheal

Acromegaly is a rare clinical syndrome caused by overproduction of growth hormone. The incidence of acromegaly has been estimated to be 3–4 patients per million.[1] In the anaesthesia literature the disorder is recognized as one cause of difficulty in airway management and tracheal intubation.[2 3] The anatomical changes that may result in a difficult or failed intubation include prognathism, macroglossia, thickening of the pharyngeal and laryngeal soft tissues and the vocal cords, fixation of the vocal cords, palsy of the recurrent laryngeal nerve, decrease of the width of the cricoid arch and hypertrophy of the arytenoepiglottic and ventricular folds.[3] However, difficulties encountered in tracheal intubation in patients with acromegaly are not well documented; only case reports in such patients have been published.[4–6] According to Ovassapian, Doka and Romsa, fibreoptic intubation can be used to avoid unnecessary tracheostomy in patients with acromegaly.[7]

In this prospective study we have evaluated orotracheal intubation conditions with a laryngoscope and a fibrescope under general anaesthesia and neuromuscular block in acromegalic patients. The patients served as their own controls.

Patients and methods

The study was approved by the Ethics Committee of the Neurosurgical Clinic at Helsinki University Central Hospital. Informed consent was obtained from all patients. Over a 3-yr period, we studied all patients presenting for surgery as a result of acromegaly. The clinical diagnosis was confirmed at the Department of Internal Medicine.

Patients were premedicated with diazepam 10–20 mg orally approximately 1 h before the start of anaesthesia. One patient received no premedication because of sleep apnoea syndrome. In the operating room ECG and haemoglobin oxygen saturation (pulse oximetry) were monitored continuously.

Glycopyrrolate 0.2 mg i.v. was administered to reduce oropharyngeal secretions. After induction of general anaesthesia with thiopental and fentanyl in doses required clinically, vecuronium, pancuronium or rocuronium was used for neuromuscular block. The patient's lungs were ventilated via a face mask. Ease of ventilation was assessed and recorded: 1=easy; 2=minor difficulties; 3=very difficult, necessitating the use of an oral airway; and 4=ventilation unsuccessful. As soon as neuromuscular block was complete (TOF), laryngoscopy was performed using a Macintosh laryngoscope with a size 5 blade. The best view achieved with or without cricoid pressure was assessed according to the grading of Cormack and Lehane[8]: 1=vocal cords visible; 2=posterior part of the vocal cords visible; 3=only the tip of the epiglottis visible; and 4=epiglottis not visible. We assumed that tracheal intubation with the Macintosh laryngoscope would have been difficult or even impossible in patients with grades 3 or 4. After laryngoscopy the patient's lungs were ventilated with a face mask.

Thereafter the large size oral Berman intubating airway (Hudson, USA) was placed into the patient's mouth. The patient's jaw was lifted upwards by an assistant nurse or physician to make a view of the larynx possible. The preformed tracheal tube (Portex, id 7 or 8) was mounted over the fibrescope (Pentax FB-15P, diameter of the insertion cord 4.9 mm) and the fibrescope was advanced via the oral airway to a depth of approximately 10–12 cm. The first view at fibrescopy was recorded: 1=vocal cords; 2=mucus membrane; 3=base of the tongue; and 4=an obscure view. The instrument was guided towards the vocal cords and into the trachea. If the fibrescope could not

be advanced into the trachea in 30 s, the procedure was interrupted for ventilation and oxygenation. A maximum of three attempts was allowed. If fibrescopy was unsuccessful, the oral airway was removed and the patient's tongue was pulled, as described by Smith, MacKenzie and Scott-Knight.[9] Jaw lift was maintained, and a 30-s fibrescopy was attempted no more than three times. The first view for each attempt was assessed as above. Times were recorded using a stopwatch by a physician or nurse.

As soon as the tip of the fibrescope was in the trachea close to the carina, the intubation tube was railroaded into the trachea. The number of fibrescope attempts was recorded. If resistance to the tracheal tube was encountered during intubation, the tube was manipulated as described in our previous study.[10] Any impingement or manipulations needed to complete tracheal intubation were recorded.

If fibreoptic intubation with the above techniques failed, the patient's trachea was intubated with the help of a rigid laryngoscope. In cases of difficult laryngoscopy, any acceptable technique to establish an airway was allowed, and a note was made. Intubations were performed by any of the authors, all being experienced with the fibreoptic technique.

For analysis of the data, the Spearman rank correlation or Fisher's exact test was used. $P<0.05$ was considered statistically significant.

Results

We studied 15 patients (nine females, six males) and every patient served as his or her own control for laryngoscopy using a size 5 Macintosh blade and a flexible fibrescope. Mean age of the subjects was 53 (range 22–68) yr. Mean weight and height were 85 (SD 19) kg and 173 (7) cm, respectively. All patients had typical manifestations of acromegaly.

Anaesthesia was induced with a mean dose of thiopental 6.3 mg kg^{-1} and fentanyl 3.7 μg kg^{-1}. Ventilation with a face mask was successful in all patients, and was easy on five occasions. An oral airway was needed in four cases. The ease of mask ventilation was not associated with subsequent intubation difficulties. The best view at laryngoscopy was graded as 1 in four patients, 2 in six (in three of whom the posterior part of the vocal cords was seen with cricoid pressure), 3 in four and 4 in one patient. When the best views at laryngoscopy were grouped as 1 and 2 denoting those in whom intubation with the aid of a Macintosh blade would be successful, and 3 and 4 as those in whom intubation would be difficult or fail, the vocal cords could be seen with the fibrescope in all but one of the latter group. The grade was associated significantly ($P<0.05$) with the number of attempts required to see the vocal cords with the fibrescope (fig. 1). None of the patients with view 1 at laryngoscopy required more than one fibrescope attempt. The first fibrescope attempt was successful in six of nine females and in three of six male patients (ns).

The frequency of resistance to the tracheal tube was eight of 15 patients (five females and three males) (ns). Manipulations led to oesophageal intubation in one instance but subsequent intubation with the help of the fibrescope was successful. On one occasion the manipulations did not lead to tracheal intubation and the patient's trachea was intubated with the help of a laryngoscope. One fibrescope attempt failed and the trachea was intubated blindly with a laryngoscope and introducer. A summary of the views at laryngoscopy, number of fibrescope attempts and impingements are presented in table 1.

None of the patients became desaturated (oxygen saturation <90%) during the study. After surgery the trachea was extubated successfully in the operating room without respiratory distress.

Discussion

Our results showed that fibreoptic intubation may prove difficult or fail in acromegalic patients. Even more important, difficulty in seeing the vocal cords with the fibrescope were encountered in patients with a grade 2–4 view at rigid laryngoscopy. In general, the causes of problems in advancing the fibrescope towards the larynx and to the trachea are blood and secretions in the oropharynx, distorted anatomy of the upper airway or inexperience with the technique.[2] Furthermore, the choice of oral airway can affect the ease of seeing the vocal cords.[11] In our study, in one case an Ovassapian airway was needed to complete fibrescopy. The tongue pulling method as an alternative to an oral airway has been used successfully by Smith, MacKenzie and Scott-Knight.[9] We found tongue pulling an acceptable option on two occasions, but in one patient with limited mouth opening, the tongue was too large to allow free advancement of the fibrescope to the oropharynx and further to the trachea.

Difficulties in seeing the vocal cords (i.e. best view graded 3 or 4[8]) with the conventional Macintosh laryngoscope were encountered in five of the 15 acromegalic patients. A grade different from that presented by Cormack and Lehane was used to assess the view at fibrescopy for several reasons: the first fibreoptic view is affected by the type of fibrescope, the model of the intubating airway (if it is used), force of jaw thrust and depth of advancement of the fibrescope. There are no reports on the incidence of difficult airway in acromegalic patients. Our findings suggest that intubation difficulties may occur more often in this group of patients than in those presenting for general surgery.[12–14] The number of patients is small because of the low incidence of the disease.[1] However, each subject served as his or her own control to assess the ease of seeing the vocal cords with each technique.

Lack of preoperative assessment of the airway can be considered a possible weakness of our report. However, the aim of the study was to evaluate the applicability of fibreoptic intubation in this group of patients, and in our opinion, the most commonly used tests for prediction of intubation difficulties do not apply to fibreoptic intubation. In fact, prediction of difficult fibreoptic intubation has not been studied, probably because the technique has been recognized as one of the best methods to manage a difficult airway.[15]

Fibreoptic intubation can prove difficult or fail, regardless of the ability to see the vocal cords.[15] In the present study the frequency of resistance to the tracheal tube was higher (eight of 15 patients) than expected from our previous results (five of 44 cases). The size of the tubes and type of fibrescopes used were similar to those in the present study.[10] We encountered impingement of the tracheal tube on eight occasions, and in seven manipulations led to successful intubation. One fibreoptic intubation failed. The causes of resistance to the tracheal tube on intubation with the fibrescope are not well elucidated. The design of the tip of the tracheal tube may explain some of the difficulties.[16] For trans-sphenoidal surgery a preformed tube is preferred, and tubes with a standard tip are the only ones available commercially. An armoured flexible tube may be an option,[17] but unpublished observations showed that intubation difficulties were not avoided by the use of such a tube (Hakala, Randell and Valli, unpublished observations). The size of the tracheal tube in relation to the outer diameter of the fibrescope has been shown to affect the rate of impingement.[10 18]

The method of choice for intubation in acromegalic patients remains unclear. Although we did not experience any case of inability to ventilate the lungs with a face mask, this risk must be taken into consideration. Similarly, in case reports of three patients, ventilation with a face mask was successful, but one difficult intubation was encountered.[4] When a difficult intubation with a Macintosh laryngoscope is anticipated, techniques other than managing the airway with a fibrescope should also be considered. Awake intubation under topical anaesthesia and sedation is the safest way to proceed if difficulties in ventilation and intubation are expected. Fibreoptic intubation in patients with acromegaly requires expertise and knowledge of alternative ways to guide the instrument towards the trachea, and manipulations of the tracheal tube are likely to lead to successful intubation on impingement.

LABORATORY INVESTIGATIONS

Effect of continuous spinal remifentanil infusion on behaviour and spinal glutamate release evoked by subcutaneous formalin in the rat

H. BUERKLE, M. MARSALA AND T. L. YAKSH

Summary

Injection of formalin into the hind paw of the rat evokes a biphasic nociceptive behavioural response, which is considered to be an animal model of postoperative pain in humans. The initial response (phase 1) is caused by activation of peripheral nociceptors and is followed by a second phase attributed to ongoing activity in primary afferents and increased sensitivity of dorsal horn neurones. The latter effect is thought to result from glutamate-mediated *N*-methyl-D-aspartate receptor activation. In studies to date it has been difficult to discriminate mechanisms underlying phase 1 and phase 2 events because of the long-lasting half-times of intrathecally administered opioids. To further understanding of the opioid pharmacology of the two different phases of the formalin test, we have studied behavioural activity and spinal glutamate release after intrathecal administration of remifentanil, a new short-lasting μ opioid. Intrathecal remifentanil 3 μg μl^{-1} min^{-1} delivered during phase 1 inhibited behavioural response during phase 1 (100%), but did not abolish subsequent phase 2 behavioural activity completely (67 (12) %). Intrathecal remifentanil administered separately in phase 1 and phase 2 revealed a similar ED$_{50}$ (0.2 μg μl^{-1} min^{-1}) for inhibition of the behavioural responses. *In vivo*, spinal microdialysis showed incomplete reduction in glutamate concentrations in response to intrathecal remifentanil administration; this in turn inhibited phase 1 behavioural responses. Therefore we contend that supramaximal doses of intrathecal remifentanil sufficient to inhibit phase 1 activity still permitted sufficient glutamate release to allow spinal facilitation. Incomplete suppression of spinal excitatory neurotransmitter release by intrathecal opioids is consistent with spinal wind-up that is triggered during phase 1 and results in phase 2 afferent drive. This might reflect one of the mechanisms underlying postoperative pain. (*Br. J. Anaesth.* 1998; **80**: 348–353)

Keywords: pain, experimental; analgesics opioid, remifentanil; rat

The formalin test as a preclinical model of tonic persistent inflammatory pain is a well established model of postoperative inflammatory pain licking.[1-3] Subcutaneous injection of formalin into the paw evokes a biphasic behavioural response: phase 1 starts immediately after formalin injection and is characterized by paw flinching and licking. After a short period of quiescence this is followed by a second phase of paw flinching and licking.[1,2,4,5] Intrathecal delivery of *N*-methyl-D-aspartate (NMDA) receptor antagonists before injection of formalin, but not between phases 1 and 2, diminished markedly phase 2. This observation has led to the suggestion that phase 2 depends on the acute release of the excitatory neurotransmitter glutamate from neurones during the initial afferent barrage.[6-12] Indeed, in previous work by Malmberg and Yaksh in conscious rats using an intrathecal loop dialysis system, it was demonstrated that glutamate concentrations increased acutely during phase 1, but not during phase 2.[6] In this study intrathecal morphine delivered before phase 1 reduced behavioural response in phase 1 and continued to suppress phase 2 behaviour even though opioid receptor antagonism was accomplished between phase 1 and phase 2.[6] A major limitation of this study was the use of naloxone to confine opioid activity to the time period of phase 1. Thus, interfering interactions with other endogenous transmitter systems in inflammatory pain mechanisms would also be lost.

In a previous study we were able to demonstrate rapid onset of analgesia by intrathecal administration of the new short-lasting μ opioid, remifentanil, within 12 min after the start of a continuous infusion followed by a concomitant fast rate of recovery within 7 min after termination of the infusion.[15] Therefore, a more precise test to examine transient activation of the spinal opioid receptor can be achieved using this new μ opioid which, because of its rapid metabolism, allows opioid activity to be confined to phase 1 of the formalin test.[14,15] Moreover, we speculate that doses of intrathecal remifentanil that suppress behavioural responses in phase 1 should result in concurrent inhibition of glutamate release.

Materials and methods

The study was approved by the Institutional Animal Care Committee of the University of California, San Diego. Rats (male Sprague–Dawley, Harlan Indus-

tries, Indianapolis, IN, USA; 300–350 g) were implanted with intrathecal catheters and thereafter kept in separate cages on a 12-h light–dark cycle and given water and food *ad libitum.* Each rat was implanted as described below with an intrathecal catheter or microdialysis system, or both. Animals were allocated randomly to treatment groups and were used only once. The animals were killed after the experiment was completed.

ANIMAL PREPARATION

Before surgery animals were anaesthetized with 2–3% halothane and 50% oxygen in air, breathing spontaneously via a mask. Surgical insertion of the intrathecal catheters was performed using a modified version of techniques described previously.[16] Intrathecal catheters were made of polyethylene tubing (PE-10, id 0.28 mm, od 0.61 mm) tied at one end into a small knot for fixation under the skin. After shaving and preliminary cleaning of the surgical area with alcohol and betadine, the rat was placed in a stereotaxic apparatus. After incision of the atlanto-occipital membrane, the intrathecal catheter was inserted into the intrathecal space and passed to the rostral edge of the lumbar enlargement, 8.5 cm posterior to the cisterna magna. The external arm of the catheter was then tunnelled subcutaneously and fixed under a skin suture. Only animals with normal motor functions were used in the experiments.

BEHAVIOURAL TESTING: FORMALIN TEST

For behavioural testing conscious rats were connected to different intrathecal catheters (see below) and placed in round Plexiglass cages (9 × 35 cm) on top of a temperature-maintained glass surface (30 °C). A mirror was set up to improve visibility of the animal's behavioural responses. An adaptation period of 15 min was allowed, and then each animal was picked up gently by another investigator and 50 µl of 5% formalin were injected s.c. into the right hind paw. The animal was replaced in its cage. Flinches of the right hind paw without concomitant movement of the left hind paw or stepping motion were counted as behavioural response and were evaluated at 1–2, 5–6, 9–10 and 14–15 min, and continued at 5-min intervals up to 60 min after injection of formalin. The interval from 0–10 min was defined as phase 1 of the formalin test (acute C-fibre stimulation) and the interval from 10–60 min was defined as phase 2.

CONSTRUCTION OF MICRODIALYSIS CATHETER

Intrathecal loop dialysis catheters were constructed from hollow fibres (200 µm id, 300 µm od, 11 kDa molecular weight cut-off; Filtral, AN 69-HF). An 18-cm length of fibre was coated with a thin layer of epoxy (Devcon Corp., Danvers, MA, USA) except for a 4-cm portion in the middle. Nichrome-Formvar wire (0.0026 mm; A-M systems, INC., Everret, WA, USA) was passed through the fibre and both ends of the fibre were attached to pieces of silicon PE-10 (3.5 cm length) with cyanoacrylate (Borden, Inc., Columbus, OH, USA). The fibre was then bent such that the uncoated portion formed a "U"-shaped loop. Finally, both pieces of silicon PE-10 were bound together with silicon rubber at the level of their junction with the dialysis fibre.[17 18]

IMPLANTATION OF THE CATHETER

To implant the microdialysis catheter, a technique similar to that described for placement of intrathecal catheters was used.[17 18] After the surgical procedures, a recovery period of 5 days was allowed before initiating sampling and testing of dialysate. The neurological status of the animal was assessed after surgery and before dialysate testing; neurological status was evaluated after flushing the intrathecal catheter with 10 µl of normal saline. Animals with impaired motor function were killed.

PERFUSION OF CATHETERS

To initiate dialysis, one of the externalized silicon PE-10 connections was attached to a 50-cm length of PE-10 tubing (inflow) and the other arm to a 50-cm length of PE-10 (outflow). A syringe pump (Harvard Compact Infusion Pump, Model 975, MA, USA) fitted with a 5-cc plastic syringe was used to perfuse the dialysis tubing with artificial cerebrospinal fluid (ACSF) at a rate of 10 µl min^{-1}. ACSF contained (nmol litre^{-1}): Na^+ 151.1, K^+ 2.6, Mg^{2+} 0.9, Ca^{2+} 1.3, Cl^- 122.7, HCO$_3$ 21.0, HPO$_4$ 2.5 and glucose 3.5. ACSF was bubbled with 95% oxygen–5% carbon dioxide before each experiment to adjust the final pH to 7.2. All experimental manipulations were preceded by a 30-min washout period and collection of two control samples (10 min each).[17]

SAMPLE COLLECTION AND ANALYSIS

Dialysate samples were collected on ice and kept frozen at −20 °C until analysed for amino acids. All dialysis samples were analysed routinely for glutamate content using the PITC (phenyl isothiocyanate) derivatization procedure and a Waters HPLC with a reverse phase C18 column (3.9 × 300 mm, 4-µm particle) and UV detector. Amino acid content was measured in single 25-µl aliquots of dialysate. Methionine sulphone was added to each dialysate sample as an internal standard. Sensitivity was 5–10 pmol/injection. Amino acid peak heights were normalized initially to the methionine sulphone peak and then quantified based on a linear relationship between peak height and amounts of corresponding standards. External standards were run daily.

FORMALIN TEST AND INTRATHECAL PERFUSION IN AWAKE ANIMALS

Formalin was injected s.c. into the hind paw after the microdialysis system was perfused for 30 min (washout period) and two baseline samples (10-min duration each) were collected. After injection, samples were collected at 10-min intervals until 20 min after injection and then at 20-min intervals after injection (samples until 10 min=phase 1, samples from 10 to 60 min=phase 2).

DRUGS

Drugs given intrathecally in this study were remifentanil HCl (molecular weight=369) (Glaxo, Research

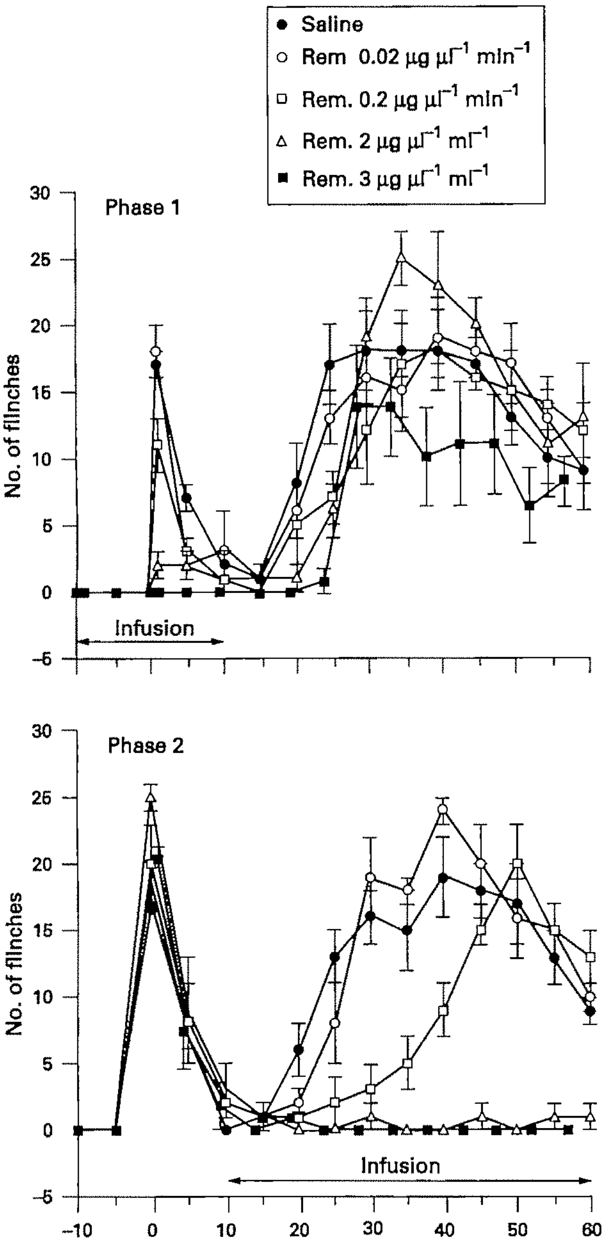

Figure 1 Time–effect curves for intrathecal infusion of remifentanil (Rem.) during phases 1 and 2 of the formalin test. The behavioural time–effect curves with intrathecal administration of remifentanil during phases 1 (−10 until +10 min) (top) and 2 (from 10 until 60 min after formalin injection) (bottom) of the formalin test are shown. The number of flinches per minute after injection of 5% formalin 50 μl s.c. in the hind paw are given. Formalin injection was performed at 0 min. Data are mean (SEM) of 5–8 animals.

Triangle Park, NC, USA) and normal saline as control. Intrathecal remifentanil infusion rates are expressed in μg μl^{-1} min^{-1}. Intrathecal injection was achieved by connecting the animal to a microinjection syringe pump (Harvard Instruments) before testing via a length of calibrated PE-50 tubing. Intrathecal drug was injected at a flow rate of 1.0 μl min^{-1}. Thus the lowest total amount of intrathecal remifentanil was 0.4 μg for the phase 1 infusion of 0.02 μg μl^{-1} min^{-1}; the highest amount for phase 1 (3 μg μl^{-1} min^{-1}) was remifentanil 60 μg.

In a separate experiment, animals receiving a supramaximal dose of intrathecal remifentanil for phase 1 suppression were given naloxone (Dupont Pharmaceutical, Wilembur, USA) 0.5 mg/kg body weight i.p., 10 min after injection of formalin. This experiment served as a control for residual intrathecal remifentanil activity affecting phase 2. All drugs were dissolved in sterile normal saline.

STATISTICAL ANALYSIS

Behavioural data are expressed as mean (SEM) number of flinches per minute for 1, 5, 10, 15 min, and at 5-min intervals up to 60 min. Statistical analysis of the behavioural data was performed using the one-way ANOVA test followed by the Student's Newman–Keuls multiple comparisons test. For illustration, the dialysate group was calculated as percentage change in baseline values (mean (SEM)). Statistical analysis of glutamate release was performed by the Kruskal–Wallace test. For all statistics, $P<0.05$ was considered significant. Dose–response curves are presented as percentage of the maximal possible effect (%MPE). For all drugs, the dose–response analysis, as described by Tallarida and Murray, was performed.[19] ED$_{50}$ and 95% confidence intervals were calculated using the least squares linear regression model, where the log dose values were used.[19]

Results

INTRATHECAL INFUSION OF REMIFENTANIL BEFORE AND DURING PHASE 1

Injection of formalin resulted in a biphasic incidence of flinching of the formalin injected paw, as demonstrated in the animals receiving intrathecal saline infusion during phases 1 and 2 (fig. 1). Intrathecal infusion of remifentanil during phase 1 and intrathecal saline during phase 2 resulted in complete dose-dependent suppression of phase 1 behaviour ($P<0.05$ compared with saline controls).

Intrathecal remifentanil at the highest dose (3 μg μl^{-1} min^{-1}) during phase 1 resulted in an approximate 40% reduction in the magnitude of phase 2 behaviour compared with the control groups (fig. 2) ($P<0.05$). To emphasize that depression of phase 2 did not result from residual action of remifentanil during phase 2, studies with phase 1 intrathecal remifentanil infusions were repeated with administration of naloxone 0.5 mg kg^{-1} i.p., 10 min after injection of formalin. Phase 2 suppression was unaltered, emphasizing that the persistent effects were not caused by residual opioid agonist action during the second phase (see fig. 2).

INTRATHECAL INFUSION OF REMIFENTANIL DURING PHASE 2

Intrathecal infusion of saline in phase 1 and intrathecal infusion of remifentanil during phase 2 revealed no difference in phase 1 behaviour compared with control animals ($P>0.05$), whereas remifentanil blocked phase 2 of the formalin test in a dose-dependent manner (intrathecal remifentanil 0.2, 2.0 and 3 μg μl^{-1} min^{-1}; $P<0.05$) (see fig. 1). The ED$_{50}$ for remifentanil was similar for suppression of both phases (phases 1 and 2: 0.2 μg μl^{-1} min^{-1} (95% CI 0.1–0.4 μg μl^{-1} min^{-1})) (fig. 3).

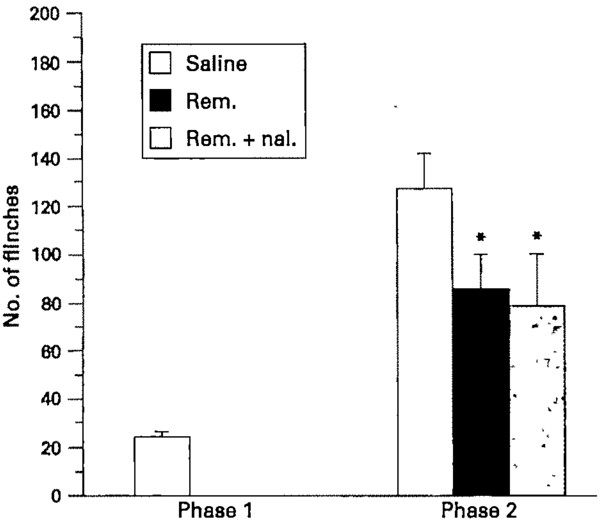

Figure 2 Behavioural activity in phase 2 after intrathecal administration of remifentanil $3\ \mu g\ \mu l^{-1}\ min^{-1}$ in phase 1 followed by naloxone i.p. Behavioural activity is expressed as number of flinches during phases 1 and 2 after phase 1 intrathecal continuous delivery of saline, remifentanil (Rem.) alone or remifentanil $3\ \mu g\ \mu l^{-1}\ min^{-1}$ followed by naloxone (nal.) i.p. As indicated for intrathecal remifentanil, no behavioural activity was observed during phase 1 and no difference was seen in phase 2 activity for animals treated with naloxone. Data are mean (SEM) of 5–8 animals. *Significant reduction in phase 1 behaviour in animals given intrathecal remifentanil compared with control animals ($P<0.05$).

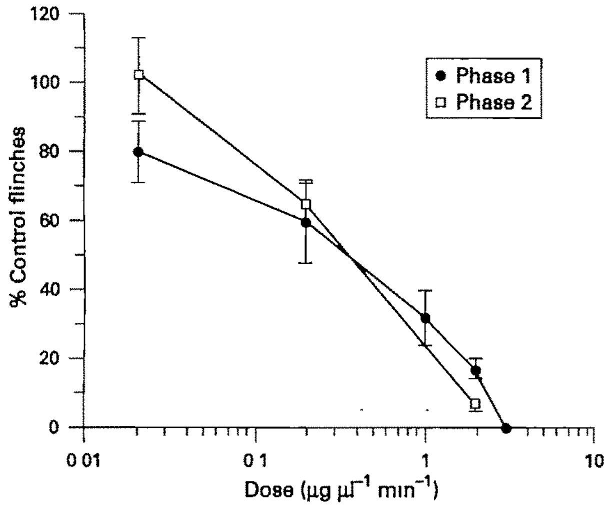

Figure 3 Dose–response curves of intrathecal remifentanil for inhibition of phase 1 and phase 2 behavioural activity. The dose–response curves for intrathecal delivery of remifentanil in phases 1 and 2 to suppress behavioural activity in each phase are shown. Data are mean (SEM) of 5–8 animals.

SPINAL GLUTAMATE RELEASE

Before treatment, measurable glutamate concentrations were present in the spinal dialysate of the unanaesthetized rat with stable baselines for saline control and intrathecal remifentanil groups. Formalin injection resulted in an increase in glutamate concentrations, which was consistently evident during the first 10 min after formalin injection in the intrathecal saline compared with the intrathecal remifentanil group (71 (34) % *vs* 21 (36) %; $P<0.05$). This release corresponded to the appearance of phase 1 behaviour. After phase 1, glutamate concentrations decreased and reached baseline values during phase 2 in both groups (fig. 4).

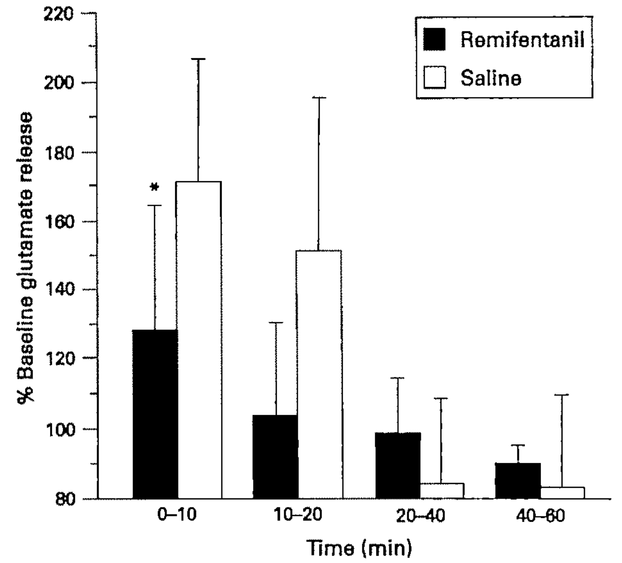

Figure 4 Intrathecal remifentanil during phase 1 and glutamate release during both phases of the formalin test. Release of glutamate in phases 1 and 2 after intrathecal administration of remifentanil $3\ \mu g\ \mu l^{-1}\ min^{-1}$ or intrathecal saline $1\ \mu l\ min^{-1}$ during phase 1 is shown. Glutamate concentrations were assessed by *in vivo* spinal microdialysis and calculated as change in percentage over baseline concentrations for intrathecal administration of saline or remifentanil. *Significant reduction in glutamate release for the intrathecal remifentanil group ($P<0.05$). Data are mean (SEM) of eight animals.

Discussion

The formalin test has been used widely as a model of inflammatory pain[1 2] to investigate the mechanisms and pharmacology of spinal facilitation. Assessment of peripheral afferent activity has emphasized that injection of the irritant formalin leads to an acute barrage of small primary afferents followed by low level, but persistent, afferent activity. The corresponding activity in dorsal horn neurones[21] and behaviour sequelae suggests a second phase of behaviour that is unexpectedly prominent given the magnitude of the afferent input during this second phase. The ability to reduce (but not completely block) this second phase by spinal delivery of NMDA receptor antagonists given before formalin injection is believed to reflect the role of glutamate release during this acute interval in triggering the second phase facilitation.[22] It was suggested that block of afferent activity by opioids during the first phase should diminish the second phase behavioural response.[23] In previous work, we used intrathecal morphine and blocked the opioid receptor during the second phase by delivery of naloxone between phases 1 and 2.[24] However, interpretation of these results was hindered by rebound hyperalgesia that can occur after using the antagonist naloxone.[25]

Therefore, in our study we were able to address this hypothesis more accurately by the use of the short-lasting opioid agonist remifentanil. This lipid soluble agent is cleared rapidly from the intrathecal space and metabolized in plasma by plasma esterases.[15 26] As we have shown previously in the rat model, continuous infusion of remifentanil rapidly achieves steady state levels within approximately 5–10 min and shows also a concomitantly fast rate of recovery after termination of remifentanil delivery.[15] Thus remifentanil appears to be useful in this model of inflammatory pain .[25 27] Further confirmation of the lack of a persistent opioid receptor occupancy by intrathecal remifentanil was obtained in our study by giving naloxone after phase 1, and the observation that naloxone had no effect on phase 2 activity. As shown previously for systemic administration of remifentanil,[27] intrathecal doses of remifentanil abolishing phase 1 behavioural activity completely did not result in complete reduction of phase 2 responses. Further increasing doses of intrathecal remifentanil during phase 1 in our study were limited by respiratory complications. Thus we suspect that the observed suppression in this model reflects the maximum achievable effect by intrathecal remifentanil. The present behavioural part of this study suggests that suppression of behaviour is not an indicator of changes during a phase 2 state of facilitatory spinal transmission.

SPINAL MICRODIALYSIS AND GLUTAMATE RELEASE

Glutamate has been shown to be the major excitatory amino acid neurotransmitter in the central nervous system, playing a key role in central sensitization and spinal pain transduction mechanisms.[28] The limitations of the dialysis model are that laminar or cellular origins of extracellular transmitters cannot be determined. In our model, glutamate concentrations have been shown to be increased in the spinal extracellular dialysate after high, but not low, intensity stimulation (Marsala and colleagues, 1995, unpublished observations). Earlier studies have shown that these increased concentrations may be suppressed by systemic morphine.[24] Accordingly, the release may derive from primary afferent or interneurones, both sources having been shown to contain this amino acid.[11 29 30]

Opioids are known to reduce small afferent transmitter release (e.g. substance P, CGRP or amino acids).[31] Thus the opioid effect observed in the present study might reflect a change in afferent glutamate secretion. On the other hand, it is believed that the NMDA receptor is postsynaptic to a non-afferent terminal.[32] Thus the opioid effect may reflect inhibition of the interneurone. Mu opioids such as remifentanil are known to induce hyperpolarization by increase in potassium conductance,[33] thereby reducing neuronal excitability. This would predictably lead to a reduction in the release of endogenous transmitters, such as glutamate, as shown during phase 1 in our study. However, even when the noxious stimulus was blocked completely, glutamate release was not abolished in the present study. This finding is in accordance with observations by Abbadie and colleagues[25] showing expression of c-*fos* in the rat spinal cord despite administration of remifentanil during phase 1 of the formalin test.

In conclusion, we have shown dose-dependent suppression of phase 1 and 2 behaviour of the formalin test after intrathecal administration of the short-lasting μ opioid remifentanil in awake animals. With regard to behavioural responses and concomitant spinal glutamate release after intrathecal remifentanil, we suggest that spinal μ opioid receptors modulate but do not abolish the mechanisms underlying spinal sensitization in this model of inflammatory pain.

Changes in right atrial catecholamine content in naïve rats and after naloxone-induced withdrawal

J. V. RABADÁN, M. V. MILANÉS AND M. L. LAORDEN

Summary

In this study, we determined if changes in heart catecholamine content during naloxone-induced withdrawal correlated with modifications in heart rate. In addition, we determined plasma concentrations of corticosterone as an index of the hypothalamo–pituitary–adrenal (HPA) axis. The effects of naloxone on norepinephrine, epinephrine or dopamine content and turnover, plasma concentrations of corticosterone and the mechanical response of the right atria of the rat were studied. Male rats were implanted with placebo or morphine pellets for 7 days. On the day of sacrifice, animals were injected with saline or naloxone 1 mg kg^{-1} s.c. to precipitate a withdrawal syndrome. Administration of naloxone to morphine-treated (tolerant) animals induced a decrease in atrial content of norepinephrine, epinephrine and dopamine (290.2 (11.9) ng g^{-1}, 15.6 (2.1) ng g^{-1} and 9.52 (0.5) ng g^{-1}, respectively) and an increase (1.38 (0.2) ng g^{-1} in the dihydroxy phenyl acetic acid/dopamine (DOPAC/DA) ratio. Administration of naloxone to morphine-treated animals enhanced plasma concentrations of corticosterone (435.8 (27.6) ng ml^{-1}). In the isolated right atria, L-naloxone induced an increase in atrial rate in preparations from morphine-treated rats whereas in placebo-pelleted (naïve) rats, L-naloxone induced a decrease. In contrast, administration of D-naloxone (inactive isomer) produced a decrease in atrial rate in preparations from placebo or morphine-treated rats. We conclude that this study has provided evidence that naloxone-induced withdrawal was characterized by activation of catecholaminergic neurones in the heart that was accompanied by an increase in atrial rate. (*Br. J. Anaesth.* 1998; **80**: 354–359)

Keywords: heart, heart rate; sympathetic nervous system, catecholamines; antagonists opioid, naloxone; rat

Chronic administration of opioids, particularly morphine, produces tolerance to many of their pharmacological effects. Physical dependence on opioids develops after repeated administration, as evidenced by the appearance of distressing physical symptoms after its withdrawal, but its intensity depends on the specific type of opioid agonist used.[1] In general, drugs acting primarily at μ opioid receptors, such as morphine and heroin, are highly addictive, whereas those acting at the κ site produce a mild degree of physical dependence.[2]

The mechanisms by which opioid tolerance and dependence develop are still not clearly understood.[3] Different mechanisms have been sought to explain the development of opioid tolerance–dependence and the effects on drug withdrawal, including adaptative changes in neurotransmitter systems that appear to be targets of opioids (for review see Nestler[4]). Several attempts have been made to ascertain the possible role of catecholamines in the genesis or expression of dependence processes. The noradrenergic system has been demonstrated to play an important role in opioid dependence and withdrawal,[4] and studies of opioid regulation of the noradrenergic system have focussed mainly on the locus coeruleus. Thus precipitation of withdrawal in morphine-dependent rats by administration of opioid antagonists caused an increase in firing of norepinephrine neurones in the locus coeruleus and an increase in the turnover of norepinephrine in the forebrain, in addition to a behavioural syndrome that has been associated with these effects.[5 6]

Also, it has been proposed that opioids can affect the activity of the hypothalamo–pituitary–adrenal (HPA) axis indirectly by altering noradrenergic neurotransmission[7 8] and attempts have been made to relate opioid-induced changes in hypothalamic noradrenergic activity to alterations in corticosterone secretion (as a marker of the HPA axis).[9 10] Moreover, it has been demonstrated that chronic administration of morphine increases the hypothalamic content of norepinephrine. However, during naloxone-induced withdrawal, the hypothalamic content of norepinephrine decreased and was accompanied by a parallel increase in plasma concentrations of corticosterone.[11 12] There is substantial evidence that noradrenergic neurones in the locus coeruleus and hypothalamus are involved in opioid dependence and withdrawal,[5 12] yet little data are available on the cardiovascular changes during morphine tolerance or dependence. It has been suggested that chronic administration of U-50,488H induced tolerance to cardiac function, which was not accompanied by down-regulation of κ binding sites.[13] In addition, a few studies indicated that catecholamines play an important role in the manifestation of the abstinence response in morphine-dependent rats. Thus adminis-

tration of naloxone to tolerant rats produced an increase in plasma concentrations of catecholamines.[14,15]

As the different symptoms of withdrawal may involve the central and peripheral nervous systems, in the present study we determined the changes in the content of norepinephrine, epinephrine, dopamine and its metabolite dihydroxy phenyl acetic acid (DOPAC) in the right atria during morphine tolerance and withdrawal. In addition, we examined if such changes were correlated with alterations in atrial rate in isolated right atria of the rat. As an index of HPA activity, simultaneously with atrial content of catecholamines, we measured plasma concentrations of corticosterone.

Materials and methods

The study was approved by the local Animal Use Committee. Male Sprague–Dawley rats (200–250 g) were housed 4–5 per cage under a 12-h light–dark cycle (light 08:00–20.00) in a room with controlled temperature (22±1 °C) and humidity (50±10%), and food and water were available *ad libitum.*

EXPERIMENTAL PROCEDURE

On the basis of previous studies,[12,16,17] rats were rendered dependent on morphine by s.c. implantation of morphine base pellets (75 mg). The implantation schedule consisted of one pellet on day 0, two pellets on day 2 and three pellets on day 4.[18] Control animals received placebo pellets (lactose) according to the same schedule. A withdrawal syndrome was induced by injecting naloxone 1 mg kg^{-1} s.c. on the morning of sacrifice (day 7) to rats implanted with morphine pellets. The control group implanted with placebo pellets was also injected with naloxone. Animals were killed 30 min after injection.

There were four experimental groups: (1) chronic placebo–acute saline s.c.; (2) chronic placebo–acute naloxone s.c.; (3) chronic morphine–acute saline s.c.; and (4) chronic morphine–acute naloxone s.c.

CORTICOSTERONE ASSAYS

At the end of treatment, rats were killed by decapitation between 09:30–10:00 to avoid circadian variations in plasma concentrations of corticosterone. Trunk blood was collected into ice-cooled tubes containing 5% EDTA and centrifuged (2500 rpm, 4 °C, 15 min). Plasma was separated and stored at −30 °C until assayed for corticosterone. Plasma concentrations of corticosterone were measured using a commercially available kit for rats (^{125}I-corticosterone radioimmunoassay, ICN, Biomedicals, USA). Inter- and intra-assay coefficients of variation were 6.5% and 4.4%, respectively. The antibody cross-reacted 100% with corticosterone and <0.5% with other steroids.

ANALYTICAL PROCEDURE FOR MEASUREMENT OF ATRIAL CATECHOLAMINES

Norepinephrine, epinephrine, dopamine and DOPAC were estimated in the right atrium of the rat by high pressure liquid chromatography with electrochemical detection (HPLC/ED, Waters Millipore, MA, USA). After decapitation, the chest was opened with a midsternal incision and the right atrium dissected and stored at −80 °C until assayed for catecholamines. The right atrium was weighed and placed immediately in a dry ice-cooled polypropylene vial and homogenized with a Polytron homogenizer (setting 5 for 30 s) in 1 ml of perchloric acid 0.1 mol $litre^{-1}$ containing EDTA 2.7 mmol $litre^{-1}$ and 3,4 dihydroxy-benzylamine (DHBA) 5 pg μl^{-1} (Waters, MA, USA) as internal standard. The homogenates were centrifuged (15 000 rpm, 4 °C, 15 min), the supernatant layer removed into a 1-ml syringe and filtered through a 0.22-μm GV (Millipore), and 10 μl of each sample injected into a 5-μm C_{18} reserve-phase column (Waters). Electrochemical detection was accomplished with a glassy carbon electrode set at a potential of +0.65 V *vs* the silver–silver chloride reference electrode. The mobile phase consisted of a 95:5 (v/v) mixture of water and methanol with sodium acetate 50 mmol $litre^{-1}$, citric acid 20 mmol $litre^{-1}$, 1-octyl-sodium sulphonate 3.75 mmol $litre^{-1}$, 9, di-n-butylamine 1 mmol $litre^{-1}$ and EDTA 0.135 mmol $litre^{-1}$, adjusted to pH 4.3. Flow rate was 0.9 ml min^{-1}. Chromatographic data were analysed with a Waters 740 date module integrator and quantified using the peak area ratio of the internal standard. Atrial content of catecholamines was expressed as ng g^{-1} wet weight of tissue.

ISOLATED RIGHT ATRIA PREPARATION

The right atrium was isolated and suspended in a 10-ml organ bath. Tyrode solution of the following composition (mmol $litre^{-1}$) was used: NaCl 136.9; KCl 5.0; $MgCl_2$ 1.05; $CaCl_2$ 1.8; NaH_2PO_4 0.4; $NaHCO_3$ 11.9; and glucose 0.5. The bathing solution was maintained at 37 °C, pH 7.4 and bubbled with 95% oxygen and 5% carbon dioxide. Each preparation was suspended under a resting tension of 0.5 g and equilibrated for 45 min before the start of the experiment. The right atrium was beating spontaneously and the frequency of contraction was measured using a force displacement transducer (Grass FT-03) and recorded on a Letica polygraph. Only preparations that had a stable basal frequency of contraction at the end of the stabilization period were accepted for study.

INDUCTION OF PHYSICAL DEPENDENCE *IN VITRO*

Concentration–response curves were constructed for naloxone 10^{-9}–10^{-5} mol $litre^{-1}$ from the right atria in rats treated chronically with morphine or placebo pellets. Concentration–response curves for D-naloxone (inactive isomer) were also constructed in both types of preparations. Concentrations of drugs were increased after a steady-state response had been attained with the previous concentration.

DRUGS

Pellets of morphine base (Alcaliber Labs., Madrid, Spain) or lactose were prepared by the Department of Pharmacy, Clinic Hospital (Madrid, Spain). Naloxone HCl (Merck, Sharp and Dome, Madrid, Spain) and D-naloxone HCl (Endo Inc. New York,

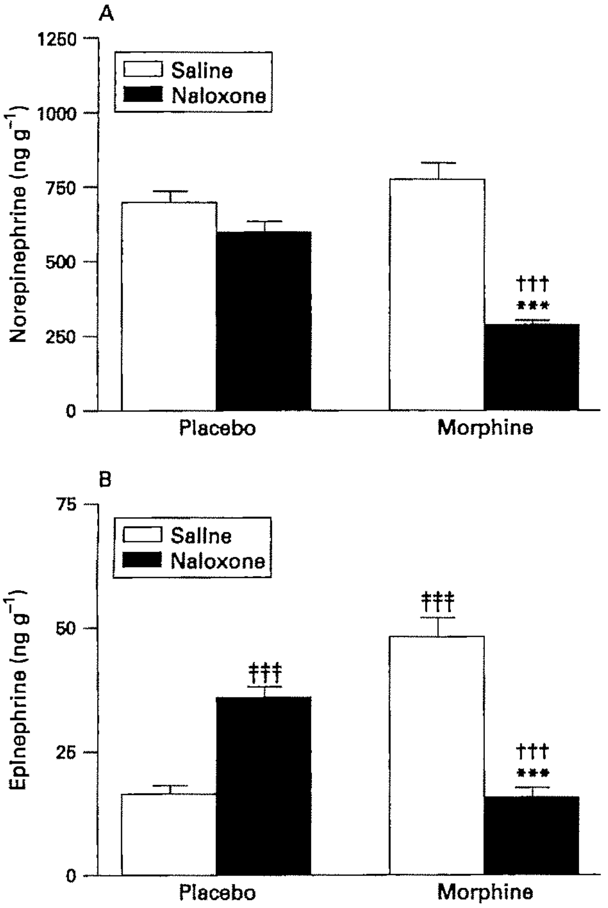

Figure 1 Atrial norepinephrine (A) and epinephrine (B) concentrations in placebo- and morphine-pelleted rats, 30 min after acute injection of saline s.c. or naloxone 1 mg kg^{-1} s.c. (mean (SEM) of 4–5 experiments). ***$P<0.001$ compared with morphine with saline; †††$P<0.001$ compared with placebo with naloxone; ‡‡‡$P<0.001$ compared with placebo with saline.

USA) were prepared fresh every day, dissolved in sterile 0.9% NaCl (saline) or distilled water, respectively. Other reagents were of HPLC grade.

STATISTICAL ANALYSIS

Data are expressed as mean (SEM). Statistical differences in the content of corticosterone, norepinephrine, epinephrine, dopamine, DOPAC and in the DOPAC/DA ratio were performed by two-way analysis of variance followed by the Newman–Keuls *post hoc* test. The results obtained *in vitro* were expressed as fractions of the change in the rate of contraction produced by a maximum dose of naloxone (mean (SEM) of *n* animals). In this case, statistical analysis was performed by one-way analysis of variance followed by the Newman–Keuls test. $P<0.05$ was considered significant.

Results

EFFECTS OF ACUTE NALOXONE ADMINISTRATION ON ATRIAL CATECHOLAMINE CONTENT AND CORTICOSTERONE RELEASE IN CHRONIC PLACEBO- OR MORPHINE-TREATED RATS

Acute administration of naloxone 1 mg kg^{-1} to morphine-treated animals decreased ($P<0.001$) atrial content of norepinephrine (290.2 (11.9) ng g^{-1}), epinephrine (15.6 (2.1) ng g^{-1}) and dopamine (9.52 (0.5) ng g^{-1}), whereas the DOPAC/DA ratio (1.38 (0.2)) increased ($P<0.001$) compared with the saline-injected group (norepinephrine 783.4 (52.2) ng g^{-1}; epinephrine 48.2 (3.6) ng g^{-1}; dopamine 37.2 (4.5) ng g^{-1}; and DOPAC/DA ratio 0.34 (0.04)). However, administration of naloxone to placebo-treated animals did not modify concentrations of norepinephrine (601.0 (27.1) ng g^{-1}), dopamine (27.6 (1.1) ng g^{-1}), DOPAC (24.9 (2.4) ng g^{-1}) or the DOPAC/DA ratio (0.9 (0.08)) but significantly ($P<0.001$) increased atrial content of epinephrine (35.6 (2.0) ng g^{-1}) compared with the respective control group injected with saline (figs 1, 2).

Plasma concentrations of corticosterone increased ($P<0.001$) 30 min after naloxone injection in morphine-treated rats (435.8 (27.6) ng ml^{-1}) compared with morphine-treated rats injected with saline (142.0 (17.5) ng ml^{-1}) or placebo-treated rats injected with naloxone (166.5 (13.3) ng ml^{-1}) (fig. 3). Plasma concentrations of corticosterone in placebo-treated rats injected with naloxone were similar to those in the respective control group given saline (168.5 (8.6) ng ml^{-1}).

EFFECTS OF NALOXONE ON ATRIAL RATE IN THE ISOLATED RIGHT ATRIA FROM CHRONICALLY PLACEBO- OR MORPHINE-TREATED RATS

In placebo-treated rats, naloxone 10^{-11}–10^{-3} mol $litre^{-1}$ decreased the frequency of contraction in a concentration-dependent manner. The maximum effect was obtained at 10^{-4} mol $litre^{-1}$ (24 (0.9) %). In contrast, in morphine-treated rats, naloxone increased atrial rate in a concentration-dependent manner, producing a maximum effect of 30 (0.1) % at 10^{-4} mol $litre^{-1}$ (fig. 4A). The inactive isomer D-naloxone induced similar effects in placebo and morphine-treated rats. Thus D-naloxone produced a decrease in atrial rate at concentrations of 10^{-11}–10^{-3} mol $litre^{-1}$ in placebo- or morphine-treated rats. In both groups the maximum effect was 30 (1.2) % (fig. 4B).

Discussion

Different methods have been used in several studies to induce opioid tolerance–dependence. In the present study, the method of morphine pellet implantation and the schedule used were similar to those described previously,[16–18] which produce a high degree of tolerance to the effects of morphine in the central nervous system. Moreover, opioid tolerance and withdrawal syndrome can be demonstrated in isolated tissues, such as in myenteric plexus longitudinal muscle (MPLM) strips from guineapig.[17 19] However, few studies have been performed in cardiac tissues.[13 20] Hence the mechanisms involved in opioid dependence in the heart are poorly understood.

In the present study the concentration–response curves to naloxone on isolated right atria were constructed approximately 1 h after isolation of the tissue and were undertaken in tissues that were set up in opioid-free Tyrode's solution. No differences in the degree of dependence have been observed in preparations that were maintained in morphine or examined in the absence of the opioid.[21] However, experiments in tissues that were bathed in a solution

containing morphine were difficult to quantify and interpret as the magnitude of the inhibitory effects produced by the maintenance concentration were unknown and therefore the degree of tolerance was also imprecise.[22]

In our study administration of naloxone to morphine-treated rats caused behavioural signs and symptoms of opioid withdrawal, such as wet-dog shakes, diarrhoea, escape jumps, teeth chattering, salivation, ptosis and irritability (data not shown). Moreover, our data showed that in morphine-treated rats, acute administration of naloxone decreased atrial content of norepinephrine, epinephrine and dopamine, whereas the ratio DOPAC/DA (an index of dopamine turnover) was increased. As expected, a large corticosterone response was observed after naloxone-induced withdrawal.

The mechanical response to naloxone in isolated right atria was different in preparations from naïve and tolerant rats. Thus in preparations from morphine-treated rats, naloxone induced a dose-dependent increase in heart rate whereas in preparations from placebo-treated rats, naloxone decreased this variable. In contrast, D-naloxone decreased the frequency of contraction in preparations from placebo- and morphine-treated rats. As D-naloxone is an inactive isomer, the decrease in the frequency of contraction obtained in our study was unlikely to be mediated via the opioid receptor. There is clear evidence that one of the autonomic symptoms of the withdrawal syndrome is tachycardia. This response could result from release of catecholamines in cardiac tissue. In addition, our results showed that chronic morphine treatment produced neuroendocrine physical dependence, as evidenced by an increase in corticosterone secretion 30 min after naloxone injection.

Several studies of opioid dependence in the central nervous system demonstrated that precipitation of withdrawal by administration of opioid antagonists to morphine-dependent rats caused an increase in firing of norepinephrine neurones in the locus coeruleus and an increase in the turnover of norepinephrine in the forebrain, in addition to a behavioural syndrome that has been associated with these effects.[5,6] Many symptoms of the autonomic nervous system which may be caused both by increasing activity of the locus coeruleus and by increased activity of spinal centres controlling sympathetic outflow.[23] In addition, chronic administration of opioids has been shown to increase concentrations of cAMP-dependent protein kinase and substrates for protein kinase, including tyrosine hydroxylase[24] (the rate-limiting enzyme in the biosynthesis of catecholamines) in the locus coeruleus. Moreover, studies in our laboratory have demonstrated that naloxone administration to tolerant rats enhanced plasma concentrations of corticosterone simultaneously with a reduction in hypothalamic content of norepinephrine.[11,12] As the paraventricular nucleus is a major area governing the output of the autonomic nervous system and ACTH secretion, the increase in corticosterone production and changes in heart catecholaminergic activity observed in our study can be attributed to a blunted response in the paraventricular nucleus.

Despite substantial evidence that noradrenergic neurones in the locus coeruleus and their projection to the hypothalamus are involved in opioid dependence and withdrawal,[4,14] there are few reports on the characteristics of functional disturbances of heart catecholaminergic neurones during opioid tolerance and dependence. Previous studies[14,15,24] have demon-

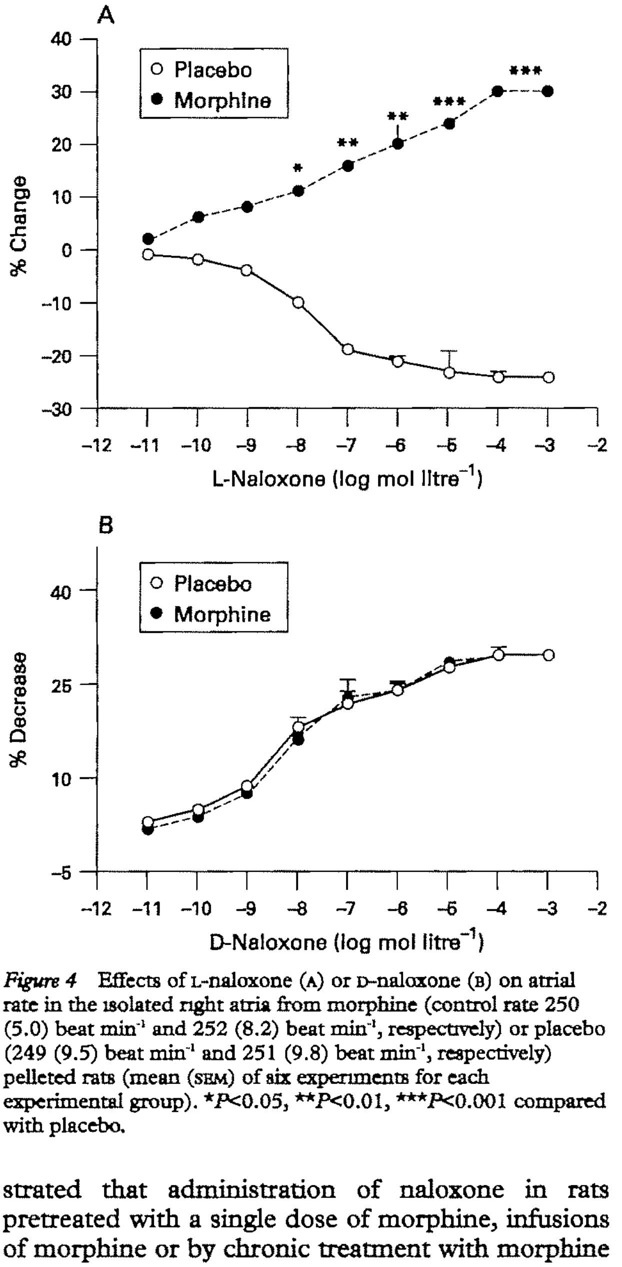

Figure 4 Effects of L-naloxone (A) or D-naloxone (B) on atrial rate in the isolated right atria from morphine (control rate 250 (5.0) beat min^{-1} and 252 (8.2) beat min^{-1}, respectively) or placebo (249 (9.5) beat min^{-1} and 251 (9.8) beat min^{-1}, respectively) pelleted rats (mean (SEM) of six experiments for each experimental group). *$P<0.05$, **$P<0.01$, ***$P<0.001$ compared with placebo.

strated that administration of naloxone in rats pretreated with a single dose of morphine, infusions of morphine or by chronic treatment with morphine pellets precipitated a withdrawal response, including an increase in mean arterial pressure, biphasic heart rate response and an increase in plasma concentrations of norepinephrine and epinephrine, suggesting that cardiovascular abstinence is mediated mostly by the catecholaminergic systems. Our results demonstrated clearly that catecholamines play an important role in the sympathetic manifestations of the abstinence response as naloxone induced a decrease in catecholamine content with an increase in dopamine turnover, which were accompanied by enhanced frequency of contraction.

However, parallel studies in guineapig ileum MPLM demonstrated that naloxone-induced withdrawal is characterized by contracture of the MPLM from morphine-treated animals.[17] Our results extend the findings in the MPLM to a different animal species, to a different physiological integrative level and to a different chain of neurotransmitter systems.

In summary, we have provided evidence that the abstinence syndrome is characterized by activation of catecholaminergic neurones in the heart that is accompanied by an increase in heart rate. We hypothesize that catecholaminergic pathways are involved in the hyperactivity of the autonomic nervous system associated with opioid withdrawal.

Surfactant impairment after mechanical ventilation with large alveolar surface area changes and effects of positive end-expiratory pressure

S. J. C. VERBRUGGE, S. H. BÖHM, D. GOMMERS, L. J. I. ZIMMERMAN AND B. LACHMANN

Summary

We have assessed the effects of overinflation on surfactant function and composition in rats undergoing ventilation for 20 min with 100% oxygen at a peak inspiratory pressure of 45 cm H_2O, with or without PEEP 10 cm H_2O (groups 45/10 and 45/0, respectively). Mean tidal volumes were 48.4 (SEM 0.3) ml kg^{-1} in group 45/0 and 18.3 (0.1) ml kg^{-1} in group 45/10. Arterial oxygenation in group 45/0 was reduced after 20 min compared with group 45/10 (305 (71) *vs* 564 (10) mm Hg); maximal compliance of the P–V curve was decreased (2.09 (0.13) *vs* 4.16 (0.35) ml cm H_2O^{-1} kg^{-1}); total lung volume at a transpulmonary pressure of 5 cm H_2O was reduced (6.5 (1.0) *vs* 18.8 (1.4) ml kg^{-1}) and the Gruenwald index was less (0.22 (0.02) *vs* 0.40 (0.05)). Bronchoalveolar lavage fluid from the group of animals who underwent ventilation without PEEP had a greater protein concentration (2.18 (0.11) *vs* 0.76 (0.22) mg ml^{-1}) and a greater minimal surface tension (37.2 (6.3) *vs* 24.5 (2.8) mN m^{-1}) than in those who underwent ventilation with PEEP. Group 45/0 had an increase in non-active to active total phosphorus compared with non-ventilated controls (0.90 (0.16) *vs* 0.30 (0.07)). We conclude that ventilation in healthy rats with peak inspiratory pressures of 45 cm H_2O without PEEP for 20 min caused severe impairment of pulmonary surfactant composition and function which can be prevented by the use of PEEP 10 cm H_2O. (*Br. J. Anaesth.* 1998; **80**: 360–364)

Keywords: ventilation, mechanical; ventilation, positive end-expiratory pressure; lung, damage; lung, surfactant; rat

Pioneering work by Mead and Collier in 1959 showed that mechanical ventilation in dogs resulted in a progressive decrease in pulmonary compliance which was reversed by periodic forced inflations.[1] Greenfield, Ebert and Benson related these changes in compliance to pulmonary surfactant by demonstrating increased surface tension in lung extracts from dogs whose lungs were ventilated with peak inspiratory pressures of 28–32 cm H_2O for 1–2 h.[2]

Intra-alveolar oedema in healthy rats subjected to intermittent positive pressure ventilation (IPPV) at high inflation pressures (HIPPV), without positive end-expiratory pressure (PEEP), was first demonstrated by Webb and Tierney[3] and later confirmed by Dreyfuss and colleagues.[4] Dreyfuss and colleagues showed that damage to lung tissue resulting in oedema formation began at the capillary endothelium and progressed rapidly to the alveolar epithelium within 20 min.[4] Using PEEP 10 cm H_2O and the same peak inspiratory pressure, the lung was partially preserved from this high permeability oedema.[4 5] A subsequent study showed that the main determinant of lung oedema formation was end-inspiratory lung volume and attributed the effect of PEEP to a decrease in lung capillary hydrostatic pressure.[6]

We postulate a different explanation for the effect of PEEP which may prevent impairment of the pulmonary surfactant system by reducing the large changes in alveolar surface area which occur during mechanical ventilation with large tidal volumes. The balance of hydrostatic forces is altered when surfactant is impaired: pressure within the alveolar fluid lining is reduced, applying more "suction" to the interstitial space. If PEEP reduces surfactant impairment, this prevents suction-induced pulmonary oedema. To assess this hypothesis, we conducted a study to measure changes in surfactant function and composition after mechanical ventilation with high lung volumes or with PEEP when changes in lung volume were less.

Materials and methods

The study was approved by the local Animal Committee, and the care and handling of the animals conformed with European Community guidelines (86/609/EC).

Twenty-four adult male Sprague–Dawley rats, weighing 290–350 g, were anaesthetized with 2% halothane and 65% nitrous oxide in oxygen, tracheotomized and a catheter inserted into a carotid artery. During the experiment anaesthesia was maintained with pentobarbital 60 mg kg^{-1} i.p. (Nembutal; Algin BV, Maassluis, the Netherlands); neuromuscular block was produced with pancuronium 2.0 mg kg^{-1} i.m. (Pavulon; Organon Technika, Boxtel, the Netherlands).

After neuromuscular block, the animals were connected to a ventilator (Servo Ventilator 300, Siemens-Elema, Solna, Sweden) in a pressure-controlled mode, at an ($F_{I_{O_2}}$) of 1.0, frequency 30 bpm and an I/E ratio of 1:2. In order to re-open the

atelectatic lung areas induced by the surgical procedure, mechanical ventilation with a peak airway pressure of 26 cm H_2O and a PEEP of 6 cm H_2O was applied for 30 s. The animals were allocated randomly to one of four groups (n = 6 in each group). Animals in group 7/0 underwent ventilation with a peak pressure of 7 cm H_2O without PEEP; group 45/0 underwent ventilation with a peak pressure of 45 cm H_2O without PEEP; and group 45/10 underwent ventilation with a peak pressure of 45 cm H_2O and a PEEP of 10 cm H_2O. Ventilatory frequency was set at 60 bpm in group 7/0 and 25 bpm in group 45/10 to maintain (Pa_{CO_2}) within the normal range. Ventilatory frequency in group 45/0 was the same as in group 45/10. The control group was killed immediately after the surgical procedure without undergoing mechanical ventilation. After ventilation for 20 min, the other animals were killed by an overdose of pentobarbital via the penile vein, followed by KCl.

Blood samples obtained from the carotid artery were measured (ABL 505, Radiometer, Copenhagen, Denmark) 1, 10 and 20 min after 30 s of ventilation with pressures of 26/6. Mean arterial pressure was measured using a Statham P23XL transducer (Spectramed, Oxnard, CA, USA) and recorded (Siemens Sirecust 404–1, Danvers, MA, USA).

During mechanical ventilation, animals were placed in a volume-constant body plethysmograph to allow continuous recording of tidal volume. A pressure transducer (Validyne model DP 45–32, Validyne Engineering Co., Northridge, CA, USA) recorded pressure changes which were sampled at 10 Hz using a 12-bit analogue-to-digital converter (DAS 1800, Keithley MetraByte, Taunton, MA, USA).

After the animals were killed, a static pressure–volume plot was recorded using conventional techniques.[7] Maximal compliance (*C*max) was defined as the steepest part of the pressure–volume deflation curve,[8] and was determined separately for each animal. The Gruenwald index, defined as $(2V_5 + V_{10})/2V\text{max}$, where V_5, V_{10} and Vmax = lung volumes above functional residual capacity (FRC) at transpulmonary pressures of 5, 10 and 35 cm H_2O, respectively, was calculated.[9] FRC was taken to be total lung volume at a transpulmonary pressure of 5 cm H_2O (V_5)[10] ; total lung weight was recorded. The lungs were lavaged with saline–$CaCl_2$ 1.5 mmol litre^{-1}.[11] The active component of surfactant in the bronchoalveolar lavage fluid was separated from the non-active surfactant component by differential centrifugation[11] followed by subsequent phosphorus analysis,[12] and the ratio of inactive to active surfactant was calculated. The protein concentration of BAL was determined using the Bradford method (Bio-Rad protein assay, Munich, Germany).[13] Some of the re-suspension (20 μl) of the active surfactant part was used for biophysical analysis of minimal surface tension after 50 cycles on a pulsating bubble surfactometer (PBS; Electronetics Corporation, Tonowanda, NY, USA), as described by Enhorning.[14]

STATISTICAL ANALYSIS

Statistical analysis was performed using the Instat 2.0 biostatistics package (GraphPad software, San Diego, CA, USA). Intra-group comparisons were analysed using ANOVA. Inter-group comparisons were analysed with repeated measures ANOVA. If ANOVA resulted in $P < 0.05$, a Bonferroni post-test was performed. All data are reported as mean (SEM).

Results

Data followed a normal distribution. Tidal volume, (Pa_{O_2}), (Pa_{CO_2}) and mean arterial pressure over time in the three groups are shown in table 1. During the study, tidal volumes differed markedly between groups (table 1). At t = 1 min, (Pa_{O_2}) was comparable in the three study groups and remained stable in groups 7/0 and 45/10; (Pa_{O_2}) in group 45/0 decreased significantly after 10 min.

Table 2 shows recovery of BAL fluid and post-mortem data for *C*max, Gruenwald index, V_5, total lung weight, total phosphorus, protein concen-

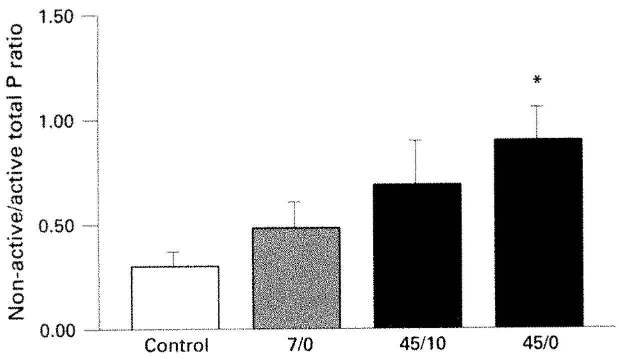

Figure 1 Ratio of non-active to active total phosphorus (P). Group 45/0 had a significant conversion of active to non-active total P during the ventilation period compared with controls. Values are mean (SEM). $*P < 0.05$ compared with the control group.

tration of BAL and minimal surface tension for the three study groups and the control group. There was no significant difference between group 7/0 and the control group for any variable. However, there were significant differences between group 7/0 and group 45/0 for all variables except total phosphorus. Figure 1 shows that the ratio of non-active to active surfactant was greater in group 45/0 compared with controls. Group 45/10 showed no impairment of any variable compared with the other groups or with controls. In addition, all variables were significantly different between groups 45/10 and 45/0.

Discussion

In this study we used an established rat model of ventilation-induced lung injury first developed by Webb and Tierney[3] and later investigated by Dreyfuss and colleagues.[4 5] The role of changes in pulmonary surfactant, however, has never been investigated in this animal model. The study was designed to better understand the relation between changes in lung morphology and permeability, and changes in the pulmonary surfactant system. We used established techniques to characterize the pulmonary surfactant system. Significant changes in surfactant function and composition occurred after lung overinflation without PEEP for a period as short as 20 min. Surfactant composition, characterized by significant conversion of active to non-active surfactant, was changed after ventilation with HIPPV, without PEEP, compared with controls who did not undergo ventilation. Impairment of surfactant function after lung overinflation was associated with impairment of lung mechanics and an increase in minimal surface tension of lung lavage fluid extracts. Impairment of surfactant composition and function caused by lung overinflation was prevented by the use of PEEP 10 cm H_2O. These findings support the hypothesis that the beneficial effect of PEEP in this model of ventilation-induced lung injury is mediated by prevention of impairment of surfactant composition and function.

Protein concentration after mechanical ventilation with high lung volumes was increased in BAL fluid in group 45/0; PEEP 10 cm H_2O prevented protein accumulation. These data are consistent with previous studies in this model which showed less accumulation of lung water, lung protein permeability and absence of intra-alveolar oedema with PEEP 10 cm H_2O during ventilation with high peak inspiratory lung volumes.[3 5]

The exact mechanism of ventilation-induced lung injury, and contributory factors, are still disputed. Experiments in rats with high peak inspiratory pressure ventilation of 45 cm H_2O, where peak inspiratory volume was limited by thorax restriction, have shown clearly that high peak inspiratory pressures alone do not induce lung injury.[5] However, a high peak inspiratory lung volume with peak inspiratory overstretching alone can also not explain ventilation-induced lung injury, as the use of PEEP 10 cm H_2O at identical peak inspiratory lung volumes almost completely prevented histologically assessed lung injury.[5] Although a role for surfactant in lung injury caused by lung overinflation was suggested,[5] our data are the first to show the association of surfactant changes in lung injury with mechanical ventilation using high lung volumes.

Several mechanisms are involved in the changes in surfactant function during mechanical ventilation. First, mechanical ventilation combined with overinflation enhances the release of surfactant from pneumocytes type II into the alveolus.[15-18] This material may be lost from the alveoli into the airways by compression of the surfactant film if the alveolar surface area becomes smaller than the surface area occupied by the surfactant molecules, so that surface-active material moves into the airways.[19 20] This mechanism of surfactant depletion after mechanical ventilation was first shown by Faridy in the isolated rat lung.[20] Mechanical ventilation increased the surface activity of lavage fluid of the pulmonary airways; this change in activity was dependent on the duration of ventilation and size of the tidal volume.[20] Studies by Wyszogrodski and colleagues have shown that PEEP prevents a decrease in lung compliance and surface activity of lung extracts, indicating prevention of loss of alveolar surfactant function during lung overinflation.[19] It was suggested that PEEP prevents alveolar collapse and thus maintains the end-expiratory volume of alveoli at a higher level, thereby preventing excessive loss of surfactant in the small airways during expiration.[21]

Second, the pulmonary surfactant system can be divided into active and non-active subfractions by differential centrifugation.[11] The active subfractions, which represent tubular, myelin-like forms of surfactant, are the metabolic precursors of the non-active components, which represent small vesicular structures.[22] Gross and Narine were the first to show that conversion of active to non-active surfactant subfractions is dependent on cyclic changes in surface area *in vitro*.[23] To maintain an adequate pool of functional surfactant subfractions in the airspaces *in vivo*, it is necessary to maintain a balance between secretion, uptake and clearance of the active and non-active surfactant subfractions.[22] Recent *in vivo* studies by Veldhuizen and colleagues in rabbits attributed surfactant conversion to a change in alveolar surface area associated with mechanical ventilation.[24 25] They found that changing ventilatory frequency[24] or the level of PEEP[25] did not affect the rate of conversion but that conversion of surfactant subfractions is dependent on tidal volume and time.[24] We found a significant conversion of active to non-active surfactant in group 45/0 compared with non-ventilated controls, but no significant conversion in the two other groups who underwent ventilation compared with controls. We suggest that the large tidal volume in group 45/0 was able to induce significant surfactant conversion within 20 min. However, this 20-min period was too short to cause a significant difference in surfactant conversion in the groups undergoing ventilation with lower tidal volumes compared with non-ventilated controls. The exact mechanisms underlying surfactant conversion as a result of changes in surface area are unknown.

An important function of pulmonary surfactant is to aid fluid balance in the lung and prevent pulmonary oedema from increased suction forces at the alveolo-capillary barrier.[26] Loss of surfactant function with an increase in surface tension at the air–liquid interphase on the alveolar walls decreases the pressure in the alveolar fluid, altering the pressure gradient across the alveolo-capillary membrane in the alveolar direction.[26–28] *In vitro* and *in vivo* studies have shown that pulmonary oedema, and in particular plasma-derived proteins in this oedema, are capable of inactivating surfactant in a dose-dependent manner.[29–32] This further decreases the pressure in the alveolar fluid and thus causes further surfactant inactivation. When this vicious circle of surfactant inactivation has started, the resulting protein-rich pulmonary oedema accounts for much of the surfactant alterations seen in group 45/0. The importance of subtle primary changes in the pulmonary surfactant system in increasing the pressure gradient across the alveolo-capillary membrane, initiating a subsequent cascade of protein inactivation, was recently shown in a model of surfactant perturbation by dioctyl sodium sulphosuccinate, which does not cause any other damage to the alveolo-capillary barrier.[28] The study also showed that changes in surfactant make the lung vulnerable to damage by mechanical ventilation.[28]

Findings in animals with induced acute respiratory failure and in patients with acute respiratory distress syndrome (ARDS) suggest that changes in the pulmonary surfactant system play a central role in this disease process.[33] Irrespective of the cause, decreased surfactant function increases the forces acting at the air–liquid interface of the alveolus and can lead to consequences such as decreased pulmonary compliance, decreased FRC with end-expiratory alveolar collapse, right-to-left shunt and hypoxaemia with anaerobic metabolism.[33] Such changes necessitate the use of mechanical ventilation to maintain adequate oxygen delivery to the tissues. Mechanical ventilation may, however, perpetuate the alterations in the pulmonary surfactant system, as found in this study, indicating that mechanical ventilation with high peak inspiratory pressures in patients with ARDS may impair the function of those alveoli that are still intact. The data also suggest that it is important to use PEEP in these patients to preserve normal surfactant function of alveoli that are not yet affected by the disease process.

We conclude that ventilation of the lungs of healthy rats with high peak inspiratory volumes at peak inspiratory pressure of 45 cm H_2O without PEEP caused severe impairment of pulmonary surfactant composition and function. PEEP prevented this impairment of the surfactant system, probably by reducing the amount of change in alveolar surface area, which prevents: surfactant displacement from the alveolar air–liquid interface into the small airways; increased conversion of active to non-active surfactant subfractions; and increased hydrostatic forces over the alveolo-capillary barrier which could lead to a self-propagating mechanism of surfactant inactivation.

Effects of inhalation anaesthetics on the release of acetylcholine in the rat cerebral cortex *in vivo*

T. SHICHINO, M. MURAKAWA, T. ADACHI, T. ARAI, Y. MIYAZAKI AND K. MORI

Summary

By analysing the EEG, reticular multi-unit activity and behavioural changes, we have classified general anaesthetics into three groups: central nervous system (CNS) depressant, CNS excitant and epileptogenic agents. Changes in CNS neural activity are associated with alteration in transmitter release. We have attempted to clarify the actions of widely used inhalation anaesthetics, such as isoflurane (CNS depressant), nitrous oxide (CNS excitant) and sevoflurane (epileptogenic) on acetylcholine (ACh) release in the cerebral cortex using brain microdialysis. ACh release was suppressed by isoflurane and sevoflurane in a dose-related manner but recovered on wash-out. There were no significant differences between the effects of sevoflurane and isoflurane at the same MAC values. In contrast, ACh release was enhanced significantly by nitrous oxide. These findings indicate that the response of the cortical cholinergic cells to different anaesthetics reflects their neurophysiological characteristics, that is whether they stimulate or suppress CNS neurones.

(*Br. J. Anaesth.* 1998; **80**: 365–370)

Keywords: anaesthetics volatile, sevoflurane; anaesthetics volatile, isoflurane; anaesthetic gases, nitrous oxide; parasympathetic system, acetylcholine; brain, cerebral cortex; rat

Acetylcholine (ACh) is one of the major excitatory neurotransmitters in the central nervous system (CNS). The activity of cholinergic neurones has long been postulated to play a key role in regulating the state of consciousness, and it has been shown that cortical ACh release decreases in the transition from wakefulness to sleep.[1] Zucker confirmed that depression of central cholinergic neurones by hemicholinium-3 and oxotremorine reduced the MAC of isoflurane and, conversely, that facilitation by physostigmine increased the MAC of isoflurane.[2]

Based on CNS electrical activities, our laboratory has classified general anaesthetics into three categories: CNS depressant, CNS excitant and epileptogenic anaesthetics.[3 4] The CNS depressant anaesthetics induced irregular alpha range slow waves (type I slow waves), the so-called barbiturate spindle bursts, which were associated with a decrease in spontaneous firing of reticular neurones. Barbiturates, halothane, methoxyflurane[4] and isoflurane[5] are members of this category. The CNS excitant anaesthetics induced rhythmic sine-curve slow waves in the theta and delta range (type II slow waves). These types of slow waves were associated with an increase in spontaneous firing of reticular neurones. Nitrous oxide, diethyl ether, cyclopropane and ketamine are included in this category.[4] With the exception of nitrous oxide, the type II slow waves were followed, not by a flattening but by a generalized electrographic, non-convulsive, high frequency, high amplitude, seizure-type activity in extremely deep planes. The epileptogenic agents resulted in type I slow waves, which were associated with a decrease in spontaneous firing of reticular neurones in light, non-convulsive planes, and spikes and electrical silence in deep, convulsive planes. The EEG spikes were associated with a phasic increase in the firing of reticular neurones, myoclonic jerking and the generalized high amplitude, high frequency activity of the seizure type, with a sustained increase in the firing of reticular neurones and generalized convulsions. Sevoflurane,[6] enflurane and gamma-hydroxybutyrate[4] are members of this category.

Using an *in vivo* microdialysis technique, we attempted to clarify the role of cholinergic neurones in the cerebral cortex during anaesthesia. One representative anaesthetic from each group was studied, that is isoflurane, sevoflurane and nitrous oxide. The development of acute tolerance to the CNS actions of nitrous oxide has been reported by us[3 7–9] and by others.[10–13] Therefore, we have also attempted to confirm if tolerance to nitrous oxide involves cortical cholinergic neurones.

Materials and methods

BRAIN DIALYSIS

The study was approved by the Animal Research Committee of Kyoto University Faculty of Medicine. We used 35 male Wister rats, weighing 250–300 g. They were housed, one per cage, under a 12-h light–dark cycle (lights on from 07:00 to 19:00) with free access to food and water. All experiments were started between 10:00 and 11:00. The animals were

anaesthetized with pentobarbital 50 mg kg^{-1} i.p. and placed on a stereotaxic frame. The skull was exposed through a midline incision of the scalp and a burr hole of 3-mm diameter was drilled. A cannula was implanted in the frontal cortex at A 3.0 mm and L 2.0 mm from the bregma, according to Paxinos and Watson,[14] and was 2.0 mm in depth. The cannula was fixed to the skull with dental cement and a stainless steel screw. The location of the probe was confirmed by visual examination of the brain at the end of each experiment. The animals were allowed to recover for at least 1 day. On the day of study, the stylet was removed from the cannula and a microdialysis probe inserted. Rats were placed in clear plastic boxes (20 × 15 × 15 cm) which were gassed continuously with 75% nitrogen and 25% oxygen (3 litre min^{-1} and 1 litre min^{-1}, respectively). The dialysis probe was connected to the perfusion pump and sample loop of an automated sample injector (model 10; EICOM, Kyoto, Japan) using polyethylene tubing. The internal standard, ethylhomocholine, delivered by the perfusion pump, was connected into the perfusate tube proximal to the injection valve. The dialysis probe was perfused continually with Ringer solution (Na^+ 147 mmol $litre^{-1}$, Ca^{2+} 2.3 mmol $litre^{-1}$, K^+ 4 mmol $litre^{-1}$, Cl^- 156 mmol $litre^{-1}$, pH 6.0) containing physostigmine 10 μmol $litre^{-1}$ at a rate of 2.0 μl min^{-1}.

Perfusate samples obtained during the first 2 h after implantation of the probe were discarded. The dialysates were then collected every 20 min in the sample loop of the automated sample injector, which was on line to an HPLC system. As analysis of ACh was complete within 20 min, the sample loop was set to be held in the load position for 20 min and was switched automatically to the injection position for 60 s, after which the cycle was repeated.

ADMINISTRATION OF ANAESTHETICS

The rats were divided into three groups for different studies.

(1) Comparison of isoflurane and sevoflurane

After 1 h of control dialysate collection, 0.5 MAC (0.75%) of isoflurane was added to the nitrogen–oxygen gas mixture for 1 h. Subsequently, the concentration of isoflurane was increased to 1.0 MAC (1.5%) and then 1.5 MAC (2.25%), with a 1-h equilibration period. One hour after discontinuation of isoflurane, 0.5 MAC (1.1%), 1.0 MAC (2.2%) and 1.5 MAC (3.3%) of sevoflurane were given for 1 h. MAC values of 2.20% sevoflurane and 1.52% isoflurane were as reported previously.[15] [16] These experiments were carried out in eight rats (group a), and then isoflurane and sevoflurane were given in reverse order to seven rats (group b). As stated below, there were no significant differences between groups a and b (data not shown), and the results from the two groups were combined.

(2) Comparison of the three anaesthetics

Ten rats were used. After 1 h of control dialysate collection, 0.3 MAC (0.7%) of sevoflurane was added to the nitrogen–oxygen mixture for 1 h and then sevoflurane was discontinued. In the same way, 1 h after stopping sevoflurane, 0.3 MAC (0.5%) of isoflurane was added for 1 h and then discontinued. One hour later, 75% nitrogen was replaced with nitrous oxide (0.3 MAC)[17] for 1 h, and then returned to the control gas mixture for 1 h.

(3) Study of long-term exposure to nitrous oxide

Ten rats were used. After 1 h of control dialysate collection, nitrogen was replaced with nitrous oxide for 4 h and then returned to the control gas mixture for 2 h.

All anaesthetics, oxygen and carbon dioxide concentrations in the box were monitored by an anaesthetic gas monitor (Type 1304; Brel and Kjaer, Denmark). Both sevoflurane and isoflurane reached expected concentrations and decreased to less than 0.1% within 5 min. Nitrous oxide reached expected concentrations and decreased to less than 2.0% within 8 min. The behaviour of the animals was observed throughout the experiments.

ACh ASSAY

ACh in the dialysates was measured using HPLC combined with an immobilized enzyme reactor and electrochemical detector, according to the method by Damsma, Westerink and Horn.[18] In brief, an Eicompak AC-Gel column (6 × 150 mm; EICOM, Japan) was used for separation. An enzymatic reactor containing acetylcholinesterase and choline oxidase, covalently attached to aminopropyl-controlled pore glass, converted ACh to hydrogen peroxide, which was detected by an electrochemical detector with a platinum electrode (model 100; EICOM) at 450 mV. The mobile phase was delivered by a pump (EP-10, EICOM) at 1.0 ml min^{-1} and contained sodium phosphate buffer 0.1 mol $litre^{-1}$ (pH 8.0), sodium 1-decansulphonate 200 mg $litre^{-1}$ and tetramethylammonium chloride 65 mg $litre^{-1}$. Quantification of the collected ACh was performed by comparison with the internal standard (ethylhomocholine) peak area.

STATISTICAL ANALYSIS

In all studies, experimental stability was confirmed by comparison of the mean initial three dialysate collections. When stability was confirmed, this served as a basal value for succeeding drug studies. When isoflurane and sevoflurane were compared, the mean value immediately before the second drug exposure was compared with those of the initial three collections. When pre-drug values did not differ from the initial three collections, this was used as the basal value in the second drug study, and data were combined with those in the first drug study using the same drug. All data are expressed as percent of basal values and represent mean (SEM). In all studies, the results were assessed for statistical significance by analysis of variance (ANOVA) with repeated measures and, when significant *F* values were obtained, Fisher's protected least significant difference (PLSD) test was used for significant differences between

treatment means. A probability level of $P < 0.05$ was considered significant.

Results

Data from eight rats (i.e. three used for comparison of isoflurane and sevoflurane, three for comparison of the three anaesthetics and two for the nitrous oxide tolerance test) were discarded because of unstable ACh release in the second or third fractions in the initial three collections by more or less than 30% of the first collection. The stability of the initial three collections of rats adopted for all drug studies was confirmed in that the differences in means of the three collections did not differ significantly. ACh content in these collections was 3.9 (0.6) pmol/20-min collection.

EFFECTS OF SEVOFLURANE, ISOFLURANE AND NITROUS OXIDE

Mean values of the initial three collections were 103.8 (4.8) %, 97.5 (8.0) % and 98.6 (9.2) % (ns). ACh release immediately before the second drug studies (93.1 (8.6) % for isoflurane and 87.0 (12.8) % for sevoflurane) did not differ significantly from those of the initial three collections for both anaesthetics. Therefore, the data were combined with those of the initial exposures. The changes in ACh release are summarized in table 1 for isoflurane and in table 2 for sevoflurane. Both anaesthetics significantly suppressed ACh release in a dose-related manner, with effects at 1.5 MAC being maximum. There were no significant differences between sevoflurane and isoflurane. ACh release was restored to control levels after discontinuation (see also fig. 1). In addition, after discontinuation of the first anaesthetic, the animals became alert, usually after 20 min, and then quiet and sleepy until the start of the second anaesthetic study, when they awoke, possibly in response to the pungency of the anaesthetic agent.

Changes in ACh release by equipotent doses of all anaesthetics and those in the recovery phases are summarized in table 3. Both sevoflurane and isoflurane suppressed ACh release significantly, and after discontinuation of both agents returned to pre-anaesthetic levels. Nitrous oxide increased ACh release significantly. After discontinuation, ACh release returned gradually, in 20–60 min, to levels not significantly different from basal. During inhalation of isoflurane and sevoflurane, animals remained still and quiet. In contrast, they became alert and moved around in response to nitrous oxide for

Nitrous oxide	158.8 (19.3)	193.7 (20.0)*	182.7 (13.8)*
After nitrous oxide	184.8 (21.8)*	133.8 (14.2)	136.5 (11.1)

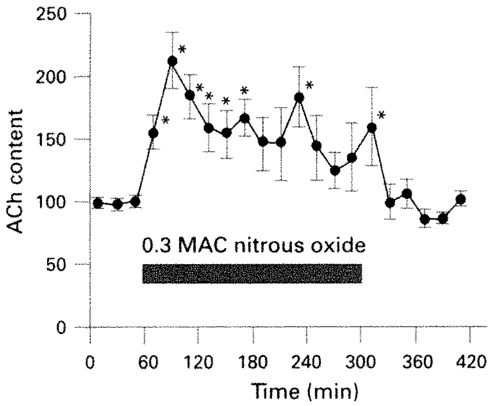

Figure 2 Effects of 0.3 MAC of nitrous oxide on ACh content in the dialysate. ACh in each fraction is expressed as a percentage of the mean of three initial collections. Data are mean (SEM) (n = 8). *P< 0.05 *vs* control.

approximately 30 min, then gradually became quiet. After discontinuation of anaesthesia, animals became alert within 5 min.

EFFECTS OF LONG-TERM EXPOSURE TO NITROUS OXIDE

Mean values of the initial three collections were 100.1 (3.0) %, 97.9 (4.3) % and 101.9 (4.3) % (ns). ACh release increased significantly to reach a maximum of 215.2 (21.0) % in the second fraction (20–40 min, $P < 0.001$), which was followed by a gradual decrease (fig. 2). After 120 min of exposure, there were no differences from the control values except for a transient increase in the ninth (160–180 min) and 13th (240–260 min) fractions. The animals became alert and moved around with inhalation of nitrous oxide for approximately 30 min, then gradually became quiet. The animals remained still and quiet for the last 180 min. After discontinuation of nitrous oxide, the animals became alert within 5 min.

Discussion

We have demonstrated that isoflurane and sevoflurane suppressed and nitrous oxide enhanced ACh release in the rat cerebral cortex. In addition, the gradual decline in the increase produced by nitrous oxide supports our hypothesis of the development of acute tolerance to this agent.

The MAC value for nitrous oxide in rats is 2.2–2.4 atm according to Gonsowski and Eger,[17] and 75% nitrous oxide in 1 atm corresponds to 0.3 MAC. This value for nitrous oxide was compared with the effects of equipotent doses, that is 0.3 MAC of isoflurane and sevoflurane, and it was confirmed that nitrous oxide enhanced ACh release while isoflurane and sevoflurane suppressed release. Our study is the first to demonstrate significant enhancement of cortical ACh release by nitrous oxide. In previous studies with other anaesthetics, Phillis reported greater rates of cortical ACh release by diethyl ether or halothane than pentobarbital or alpha-chloralose.[19] However, he did not study the dose–effect relationship, and no basis was provided for the comparison of different anaesthetics at similar depths. Recently, ketamine, another CNS excitant anaesthetic, was shown to enhance ACh release in the rat hippocampus.[20] However, the significance of this study in the hippocampus is not clear and not comparable with our study.

Decreases in striatal ACh release induced by chloral hydrate, pentobarbital and halothane were reported recently.[21 22] The significance of activities of the cholinergic cells projecting to the striatum is beyond the scope of this study. However, these agents belong to the category of CNS depressants in our classification, and their findings may have some similarity with our results. In our study, isoflurane, a depressant anaesthetic, and subconvulsive doses of sevoflurane, an epileptogenic agent, decreased ACh release in the cerebral cortex. In these two groups, the decrease in ACh release correlated with suppression of spontaneous neural activity in the CNS at non-convulsive planes of anaesthesia, suggesting that suppression of cholinergic activities is in part one of the cellular mechanisms of anaesthesia.

Although cholinergic neurones have been postulated to have key roles in the maintenance of consciousness,[1] and the rats in our study were quiet during exposure to nitrous oxide, ACh release was not suppressed but enhanced. This fact, however, does not necessarily argue against the so-called unitary theory of anaesthesia. Our view is that, although no basis is provided, the CNS neuronal network is highly integrated and intricate, and expression of anaesthetic actions may differ when different measures are used. Briefly, our view is that suppression of cortical cholinergic activity may correlate with suppression of consciousness, but the reverse is not always true and activation does not necessarily correlate with elevation in the level of vigilance.

Mori and Winters were the first to document the development of acute tolerance to nitrous oxide, based on CNS electrical activities and the wake–sleep cycle in cats.[3] This observation was followed by several reports of nitrous oxide tolerance in various brain functions in animals and humans, such as analgesic actions,[10 11 13 23 24] suppression of righting reflex,[12 25] EEG,[8] anticonvulsant actions,[7] changes in brainstem opioid receptor density,[26] activation of the dopaminergic system[9] and cortical evoked potential.[7 27 28] However, different brain functions may be affected by anaesthetics in different ways, and not all studies support the development of tolerance to all of the CNS actions of nitrous oxide.[29] The time course of the development of tolerance, if observed, varies from a few minutes[12] to more than 10 h.[11 26 28] In our studies in cats,[7] rats[9] and humans,[8] the maximum effects of nitrous oxide were observed during the first 30 min, subsiding gradually within 2 h, to reach a steady state. The time course of changes in ACh release in our study was consistent with our previous studies. However, further studies are required to determine if changes in ACh release are the cause or result of tolerance.

Previous electrophysiological studies have indicated that the CNS actions of nitrous oxide include stimulation, that is activation of reticular cell firing,[3 30] and excitation of preganglionic sympathetic fibres.[31] We have confirmed CNS excitation of cholinergic neurones by nitrous oxide. Hornbein and colleagues[32] demonstrated hyper-reactivity in human volunteers, for example catatonic jerking of the extremities during hyperbaric nitrous oxide anaesthesia (1.55 atm). Furthermore, they observed nausea and vomiting in all subjects after exposure to nitrous oxide. We have documented previously activation of the cortical and medullary dopaminergic systems in rats by nitrous oxide, and attributed activation of cortical dopaminergic cells to the euphoric action and that of the medulla to the nausea and emesis during and after short-term nitrous oxide administration.[9] Emesis is a process induced by activation of the vomiting centre in the lateral reticular formation of the medulla, which receives input from the chemoreceptor trigger zone (CTZ) in the medulla. The CTZ is richly endowed with receptors, not only for dopamine, but also for ACh.[33] We thus postulate that nitrous oxide stimulates central cholinergic and dopaminergic neuronal networks.

Several reports have suggested that delayed emergence from anaesthesia can be treated successfully with i.v. physostigmine.[34–41] Our study provides the basis for this treatment in the case of isoflurane and sevoflurane.

In summary, isoflurane and sevoflurane suppressed and nitrous oxide enhanced ACh release in the rat cerebral cortex *in vivo*. The release of ACh in this study reflects activation of cholinergic neurones projecting to the cortex and suggests that our classification of anaesthetics (CNS depressant and excitant) involves cholinergic neurones projecting to the cerebral cortex. The decrease in ACh release does not necessarily indicate that it is the basis for loss of consciousness in that nitrous oxide, which produced quiescence, did not suppress but enhanced release. The decrease in ACh release caused by CNS depressant anaesthetics gives an experimental basis for the physostigmine-induced arousal from the prolonged aftersleep following anaesthesia in the clinical setting. Moreover, the time course of changes in ACh release during exposure to nitrous oxide implicates involvement of cholinergic neurones projecting to the cerebral cortex in the development of tolerance.

REVIEW ARTICLE

Myocardial stunning in the neonate

P. D. Booker

Prolonged but reversible post-ischaemic ventricular dysfunction was first termed "myocardial stunning" in 1982 by Braunwald and Kloner.[16] This condition typically occurs after cardiac surgery where the heart has sustained ischaemic–reperfusion damage during operation. Neonates are not immune from such problems and as early primary repair, rather than palliation, of congenital heart lesions is now commonplace, prevention and treatment of myocardial stunning is increasing in importance to the paediatric cardiac anaesthetist. It was thought previously that myocardial stunning occurred only after ischaemia–reperfusion, but it is now apparent that stunning can also be caused by hypoxia–reoxygenation. Moreover, irrespective of the aetiology, the nature and consequences of myocyte injury may be modified by postnatal age. Experimental studies indicate that the immature heart exhibits greater functional recovery than the adult heart after a short period of ischaemia (fig. 1).[52 90] Conversely, experimental models of normothermic ischaemia without reperfusion have shown that newborn hearts develop ischaemic contracture earlier than adult hearts.[91] However, if reperfusion is started before the onset of contracture, newborn hearts are able to recover ventricular function and high-energy stores faster than adult hearts.[41 91] Thus the explanation for this apparent paradox is not solely related to experimental differences in duration of ischaemia time or use of different experimental end-points. Moreover, the response to ischaemia–reperfusion is significantly different between not only the newborn and the older neonate, but also between species,[1] which makes study comparisons and interpretation difficult. Compared with adults requiring cardiac surgery for acquired lesions, operative management differs for hypoxic neonates in that it is initiation of cardiopulmonary bypass (CPB), rather than reversal of ischaemia, which may provide the first stimulus for myocyte injury. Myocardial stunning can develop in the absence of previous ischaemia and cyanotic neonates are at particular risk of "reoxygenation injury" and subsequent myocardial dysfunction when CPB[17] or extracorporeal membrane oxygenation (ECMO)[42] is initiated. Experimental studies have shown that hypoxia–reoxygenation may be more injurious than a similar period of ischaemia–reperfusion,[47 93] although the hypoxic heart may have a greater tolerance of ischaemia than the normally oxygenated heart.[9] Myocardial stunning is caused by myocyte dysfunction. Generation of free radicals, resulting in damage to cellular proteins and phospholipids, and disruption of intracellular calcium homeostasis, are the two, non-mutually exclusive mechanisms responsible for this post-injury dysfunction.[33] Subsequently, disturbances in energy production or energy use, or both, by the contractile elements can be demonstrated. However, not only does the normal functioning of the immature myocyte differ from that of the adult, but the mechanism of the cellular response to injury is also different. The first part of this review examines the major physiological differences between myocytes from immature and adult hearts, and how those differences may affect the response to reversible injury. These age-related differences also dictate that the methods we use to prevent stunning, the subject of the second half of this review, may need to vary from those used in the adult.

DEVELOPMENTAL CHANGES IN SARCOLEMMAL IONIC FLUXES AND RESPONSE TO INJURY

Fluctuations in intracellular calcium ion (Ca^{++}) concentration necessary for excitation–contraction coupling are mediated by both the actions of channels in the sarcolemma and sarcoplasmic reticulum (SR). In the adult rabbit, the SR provides 90% of the Ca^{++} used to activate myofilaments.[111] The influx of Ca^{++} through voltage-dependent L-type calcium channels in the sarcolemma triggers the opening of SR Ca^{++} channels, inducing the release of large amounts of Ca^{++} from the SR.[110] In contrast, many studies using various immature mammalian heart preparations have shown that trans-sarcolemmal Ca^{++} flux is much more important than SR Ca^{++} release for the action potential-induced increases in cytosolic Ca^{++} concentration.[7 69 111] However, human neonates may have relatively mature myocytes and SR Ca^{++} release, triggered by sarcolemmal Ca^{++} flux, may assume greater significance in early postnatal life in humans than in most newborn animals.[37] Nevertheless, the smaller density of calcium current in human neonates and young children compared with adults suggests that the density of L-type calcium channels increases with postnatal age.[37] Furthermore, the rate of increase of intracellular Ca^{++} concentration,

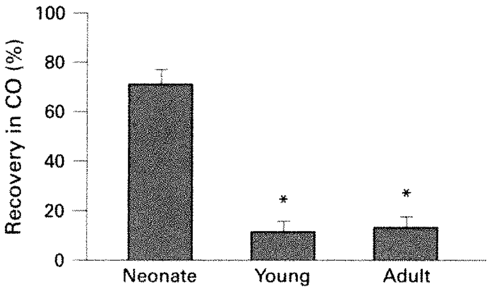

Figure 1 Isolated heart preparations obtained from rabbits aged 7–10 days (neonate), 30–40 days (young) and 6–12 months (adult) were subjected to 60 min of ischaemia at 34°C. Measurements of cardiac output (CO) obtained after 60 min of reperfusion were expressed as percentage recovery compared with pre-ischaemic values. Mean (SEM) values for the young and adult groups were significantly different from the mean neonatal value ($*P < 0.05$). Data from Pridjian and colleagues.[90]

relative to the maximum Ca^{++} concentration obtained after sarcolemmal depolarization, was found to be significantly smaller in neonates than in older children,[37] suggesting relatively low functional efficiency of SR Ca^{++} release. In immature heart preparations, much of the Ca^{++} influx through the sarcolemma is via the sodium–calcium (Na^+–Ca^{++}) exchanger, rather than L-type calcium channels (fig. 2).[7 111] The Na^+–Ca^{++} exchanger allows exchange of three Na^+ ions for each Ca^{++} ion, the relative amount of Ca^{++} removal depending on intracellular Na^+ and H^+ ion concentrations. The adenosine triphosphate (ATP)-dependent sodium pump maintains the Na^+ concentration gradient across the sarcolemma.[69] The density of Na^+–Ca^{++} exchangers in the sarcolemma of newborn mammals is species dependent, but is usually,[6 11] although not always,[7] higher than in adults. This relative abundance of Na^+–Ca^{++} exchangers correlates with the greater importance not only of this method of Ca^{++} influx during systole, but also of Ca^{++} efflux during diastole.[11 111] Factors favouring Ca^{++} influx via Na^+–Ca^{++} exchangers include prolonged sarcolemmal depolarization, decreased extracellular and increased intracellular Na^+ concentration.[111] Thus Na^+–Ca^{++} exchange may play an important role in determining Ca^{++} influx not only during cellular acidosis and ischaemia, but also during hyperkalaemic cardioplegic arrest.[25] Sarcolemmal injury, secondary to ischaemia–reperfusion, can be caused not only by free radicals but also by intracellular ATP depletion, either by its effect on channel protein function or phospholipid topology, or both.[89] Subsequent excessive inward Na^+ flux through various sarcolemmal transport pathways, including the sodium fast channels, calcium channels and the Na^+–K^+ pump, may result in intracellular Na^+ accumulation.[105] This increase in intracellular Na^+ concentration can lead to increased sarcolemmal Ca^{++} influx during ischaemia and reperfusion, secondary to Na^+–Ca^{++} exchange. Na^+–Ca^{++} exchanger activity during ischaemia–reperfusion may be greater in newborns than in adults.[73] Although acidosis partially inhibits the Na^+–Ca^{++} exchanger,[29] intracellular accumulation of Ca^{++} progressively increases if ischaemia is sustained. Experimental studies have indicated that ischaemia–reperfusion or acidosis, or both, inhibit Na^+–K^+-ATPase activity less in the newborn than in the adult.[73] However, the beneficial decrease in intracellular Na^+ and Ca^{++} accumulation this could produce is somewhat negated by a reduced basal level of activity of this enzyme in newborns.[73] Although sarcolemmal channel activity during ischaemia–reperfusion may be greater in the newborn than in the adult, both Ca^{++} influx into the cell and resting intracellular Ca^{++} concentration are determined largely by the H^+ gradient across the sarcolemma. This is because another important source of Na^+ influx is the Na^+–H^+ exchanger, particularly when there is severe intracellular acidosis induced by prolonged ischaemia–reperfusion.[116] Inhibition of Na^+–H^+ exchange is protective against ischaemia–reperfusion injury, when the H^+ ion gradient across the sarcolemma is exacerbated; it inhibits the restoration of intracellular pH and hence the Ca^{++} overload mediated by Na^+–Ca^{++} exchange.[31 38 116] Although extracellular acidosis partially inhibits the Na^+–H^+ exchanger, intracellular retention of Ca^{++} increases progressively during sustained ischaemia because this Na^+–H^+ exchange inhibition is over-ridden by the increasing intracellular acidosis.[19] Experimental studies indicate that H^+ ion extrusion from the cytosol via various sarcolemmal channels may be more efficient in the newborn than in the adult.[72 84] The ATP-dependent Ca pump in the sarcolemma does not normally transport significant amounts of Ca^{++} back out of the cell in either immature or adult hearts. Reactive oxygen intermediates, such as superoxide anion (O_2^-), may mediate both reperfusion and reoxygenation injury.[93] Hypoxia and ischaemia deplete tissue concentrations of endogenous antioxidants, increasing vulnerability to reperfusion or reoxygenation injury, or both. Reoxygenation itself

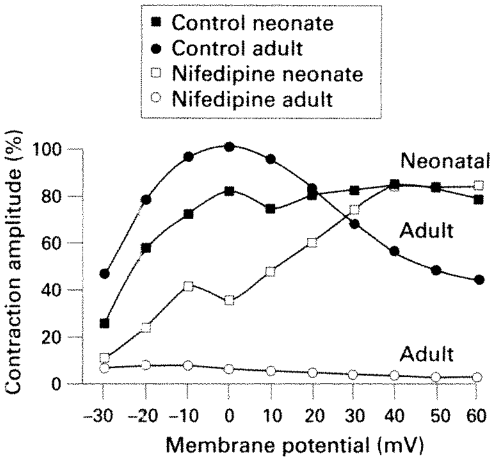

Figure 2 Isolated neonatal and adult rabbit myocytes were subjected to a series of depolarizations from a holding potential of −80 mV to various test potentials at 10-s intervals. Contraction amplitude was quantified as the maximum difference between the cell edge position before and after depolarization and expressed as mean (SEM) percentage of the normalized maximum value for each cell. The maximum contractions obtained under control conditions from neonatal myocytes were obtained at nearly all the positive membrane potentials tested, whereas myocytes from adults showed peak contraction at 0 mV with smaller depolarizations at positive membrane potentials. Exposing myocytes from neonatal rabbits to the calcium channel blocker, nifedipine, resulted in some inhibition of contractions at membrane potentials from −10 to +10 mV, but had no effect on the maximum contraction amplitude. In contrast, adult myocyte contraction was almost completely inhibited by nifedipine. At the concentration of nifedipine used (5 µmol $litre^{-1}$), Ca^{++} influx via L-type calcium channels was blocked but Na^+–Ca^{++} exchangers were unaffected. Adapted from Wetzel, Chen and Klitzner,[111] with permission.

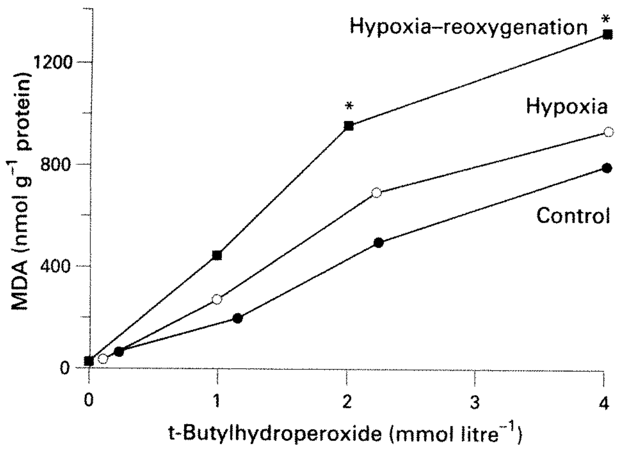

Figure 3 Left ventricular subendocardial muscle obtained from neonatal piglets before hypoxia (control), at the end of 2 h of ventilator-induced hypoxaemia and after 30 min of hypoxaemia and 60 min of reoxygenation induced during cardiopulmonary bypass was homogenized and incubated with different concentrations of the oxidant t-butylhydroperoxide. Lipid peroxidation was determined spectrophotometrically and expressed as nanomoles of malondialdehyde (MDA) per gram of protein. Lipid peroxidation after hypoxia–reoxygenation was significantly increased compared with control values at the higher concentrations of oxidant (*$P < 0.05$). Adapted from Ihnken and colleagues,[45] with permission.

may cause a further reduction in antioxidants (fig. 3). There appears to be a close correlation between antioxidant depletion, oxidant damage and cardiac dysfunction, explaining why pretreatment with antioxidants increases tolerance to reperfusion and reoxygenation injury.[77] The immature heart may be more vulnerable than the adult heart to the toxic effects of oxygen free radicals because of lower baseline concentrations of antioxidants.[85] This hypothesis is in accord with the finding that membrane damage from lipid peroxidation occurs mostly in the sarcolemmal membrane, with sarcoplasmic reticulum and mitochondrial membranes being affected to a much smaller extent.[92] Furthermore, after reperfusion injury, the newborn heart may generate more oxygen free radicals than a more mature heart.[27] The myocytes in newborns have a reduced turnover of membrane phospholipids that prevents the restoration of intact membranes from the phospholipid degradation induced by ATP depletion or free radical attack during reperfusion–reoxygenation.[105]

DEVELOPMENTAL CHANGES IN SR FUNCTION AND RESPONSE TO INJURY

In the adult, intracellular Ca^{++} concentration in the myocyte is restored to resting levels mainly as a result of SR Ca^{++}-ATPase, which binds Ca^{++} and ATP on its cytoplasmic side and translocates the cation into the SR lumen. The relative contributions of the SR pump and the Na^{+}–Ca^{++} exchanger in removing Ca^{++} from the cytosol during diastole varies among species,[69 98] but immature mammal[34] and human[37] myocytes consistently show reduced SR Ca^{++} pump activity compared with those from adult hearts. The age-related changes in myocardial relaxation and in the relaxation response to various stimuli probably relate to these limitations in SR Ca^{++} pump activity or low level of phospholamban activity, or both. None the less, the SR probably makes a significant physiological contribution to intracellular Ca^{++} flux, even in newborns. Experimental studies have produced conflicting results as to whether or not the SR in the stunned myocardium can actively take up normal amounts of Ca^{++}.[60 62] Methodological differences may account for these disparities as the capacity of SR to actively transport Ca^{++} decreases time-dependently during ischaemia.[79] However, although Ca^{++} leakage from the SR into the cytosol may occur subsequent to ischaemia–reperfusion injury in myocytes from both adult and immature hearts, excessive Ca^{++} flux across the sarcolemma is probably the predominant cause of intracellular Ca^{++} accumulation. Demonstration of a beneficial protective effect afforded by the addition of sarcolemmal calcium channel antagonists to cardioplegic solutions offers indirect confirmation of this hypothesis.[5]

DEVELOPMENTAL CHANGES IN CA^{++} UPTAKE BY THE MITOCHONDRIA AND RESPONSE TO INJURY

In the heart, mitochondria not only synthesize ATP but are involved also in the maintenance of intracellular Ca^{++} homeostasis during pathological states. The H^{+} ion electrochemical gradient that is generated by electron transport along the inner mitochondrial membrane is necessary for both processes. Furthermore, the mitochondria can be an important source of free radicals, as their electron transport train is reduced during ischaemia–reperfusion or hypoxia–reoxygenation, allowing increased leakage of electrons that can react with molecular oxygen.[33] In the adult heart, mitochondrial uptake of Ca^{++} is usually insignificant under aerobic physiological conditions, but increase in cytosolic Ca^{++} concentration in the reperfusion-injured cell leads to increased mitochondrial Ca^{++} uptake and alterations in the permeability of the inner mitochondrial membrane, resulting in swelling. Furthermore, this active Ca^{++} transport across the mitochondrial membrane inhibits utilization of the H^{+} electrochemical gradient for ATP production.[33] Mitochondria in the newborn rabbit heart show enhanced Ca^{++} uptake compared with that observed in older rabbits, even at physiological intracellular concentrations of Ca^{++}. During early neonatal life, Ca^{++} uptake by the mitochondria and phosphorylating respiratory activity decline towards adult values.[114]

DEVELOPMENTAL CHANGES IN ENERGY SUBSTRATE UTILIZATION AND RESPONSE TO INJURY

Newborn mammalian myocardium consists of small myocytes containing small mitochondria that exhibit well-coupled oxidative phosphorylation and phosphorylating respiratory activity equal to that in adults. Normally, the substrate preference of the adult heart is determined by the relative concentrations of substrates in the blood. Thus when carbohydrate concentrations are high, carbohydrate oxidation is the main energy source but, in the fasted state, the myocardium relies primarily on β-oxidation of free fatty acids.[63] In contrast, most of the energy requirements of the newborn heart are obtained from lactate oxidation and glycolysis. Experimental animal work suggests that the capacity to oxidize fatty acids and glucose is impaired in early postnatal life. However, over the first few days of life there is rapid maturation of the enzyme pathways involved in fatty acid oxidation, although glucose oxidation appears to mature at a slower rate.[65 66] The stores of myocardial glycogen in the newborn decrease soon after birth, but the ability to metabolize amino acids anaerobically is retained throughout the neonatal period; both metabolic pathways may contribute to the neonate's tolerance of hypoxia and ischaemic injury.[51] However, experimental studies have been unable to demonstrate a consistent correlation between functional recovery and tissue ATP concentration.[52 82] Furthermore, as contractile dysfunction can persist in the presence of near-normal ATP concentrations and normal mitochondrial function,[35] it would appear that energy supply is not the limiting factor preventing return of normal myocardial contractility after ischaemia–reperfusion injury. Lactate production is enhanced in immature hearts compared with adult hearts during ischaemia, but it is not known if H^+ ion production is also influenced by age. Although both anaerobic glycolysis and glycogen metabolism have lactate anions as end products, the relevant chemical reactions do not produce a net gain in H^+ ions.[28] During oxidative phosphorylation, most of the H^+ ions produced by ATP hydrolysis are used in its re-synthesis. However, when ATP is formed by glycolysis rather than by mitochondrial metabolism or creatine phosphate breakdown, H^+ ions arising from its hydrolysis are not consumed. Thus metabolic generation of protons during relatively short periods of ischaemia–reperfusion in both adult and immature hearts is primarily a result of the increased reliance on glycolysis for ATP re-synthesis. During prolonged ischaemia, however, H^+ production secondary to nucleotide degradation becomes increasingly important and is subject to developmental influences (see below). Moreover, in adults there may be some additional contribution in H^+ production related to lipolysis, membrane phosphoglyceride degradation, or both.[28] Histidine residues provide some intracellular buffering of H^+ ions, but the predominant intracellular buffer is inorganic phosphate, formed after transfer of phosphate from creatine phosphate to ADP. Unbuffered protons can leave the cell via the sarcolemmal Na^+–H^+ exchanger but interstitial proton accumulation decreases the trans-sarcolemmal H^+ ion gradient and results in a decrease in H^+, lactate ion efflux and Na^+–H^+ exchange across the sarcolemma. While tissue remains ischaemic, however, a low pH may be of benefit as it depresses SR and myofibrillar ATPase activity and thereby slows the rate of ATP use.[58] The rate of H^+ ion removal from ischaemic tissue is determined by washout. Reperfusion of ischaemic tissue, for example by cardioplegia, leads to rapid efflux of accumulated intracellular protons, resulting in secondary influx of Ca^{++} via the Na^+–Ca^{++} exchanger. Contractile failure early during ischaemia is caused by a decrease in the sensitivity of the myofilaments to Ca^{++}, together with reduced Ca^{++} flux secondary to sarcolemmal and SR calcium channel dysfunction. The decrease in myofilament sensitivity and calcium channel inhibition are caused by an increase in the intracellular concentration of inorganic phosphate and by a decrease in intracellular pH.[20 58] However, inhibition of contractile function induced by acidosis is reduced in neonates, compared with adults (fig. 4). This is because of developmental changes in SR function,[58] sarcolemmal channel activity[20] and troponin isoforms affecting the thin filament regulatory complex.[10]

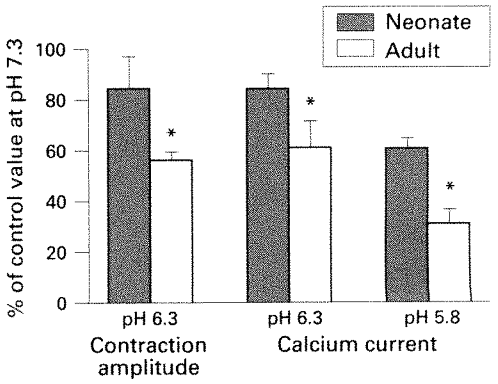

Figure 4 Effect of reducing extracellular pH on cell contraction amplitude an calcium current in isolated neonatal and adult rabbit myocytes. Results are expressed as mean (SEM) percentage (%) of control values taken at an initial pH of 7.3. All adult values were significantly different from neonatal values ($^*P<0.05$). Adapted from Chen and colleagues,[20] with permission.

DEVELOPMENTAL CHANGES IN NUCLEOTIDE SALVAGE AFTER INJURY IN THE ISCHAEMIC MYOCARDIUM

ATP is dephosphorylated to adenosine diphosphate (ADP), adenosine monophosphate (AMP) and inosine monophosphate (IMP). These precursors are unable to diffuse out of the cell and can be re-phosphorylated by viable myocytes during reperfusion to regenerate ATP. However, AMP and IMP nucleotides may be dephosphorylated to their respective precursors, adenosine and inosine, by the enzyme 5'-nucleotidase. Adenosine may either diffuse across the sarcolemma to the extracellular space or be deaminated to inosine by adenosine deaminase. Inosine may diffuse out of the cell to undergo degradation to hypoxanthine and xanthine where, as substrates for endothelial xanthine oxidase, then can form oxygen free radicals.[33] Adenine nucleotides can be restored either by relatively slow *de novo* synthesis or by faster nucleotide salvage. Reperfusion cannot replace intracellular AMP, ADP and ATP, as they are unable to be transported across the sarcolemma. The re-phosphorylation of adenosine to AMP is catalysed by the enzyme adenosine kinase, which may have a higher activity in neonates than in adults.[26] However, this nucleotide salvage pathway is possible only if adenosine is available as a precursor. Thus inadequate repletion of ATP after ischaemia–reperfusion may be caused as much by the unavailability of intracellular adenosine as by the inability of the mitochondria to phosphorylate precursors of ATP. Although reperfusion can be used to replenish intracellular adenosine, this precursor is actively transported across the sarcolemma relatively slowly and passive diffusion requires a high concentration gradient. Tissue ATP concentration and functional recovery can be enhanced after ischaemia–reperfusion if adenosine is added to cardioplegic solutions in high concentrations or endogenous adenosine concentrations are increased by inhibiting adenosine deaminase.[14] None the less, in adult rabbits, inhibition of 5'-nucleotidase preserves ATP after ischaemia–reperfusion, suggesting that nucleotide

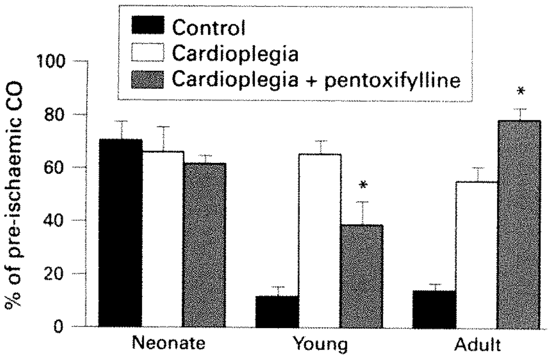

Figure 5 Isolated heart preparations from 7–10-day-old (neonate), 30–40-day-old (young) and 6–12-month-old (adult) rabbits were subjected to 60 min of ischaemia at 34°C. Control hearts from each age group received no protection, while others received either multi-dose St Thomas's Hospital cardioplegia or multidose St Thomas's Hospital cardioplegia with pentoxifylline, a 5'-nucleotidase inhibitor. Measurements of cardiac output (CO) obtained after 40 min of reperfusion are expressed as mean (SEM) percentage of pre-ischaemic values. In young and adult rabbits the values for the pentoxifylline group were significantly different from those in the cardioplegia only group ($*P < 0.05$). Data from Pridjian and colleagues.[90]

breakdown by 5'-nucleotidase may be an important mechanism of high-energy phosphate loss.[15 90] However, giving a 5'-nucleotidase inhibitor to neonatal rabbits does not improve either myocardial ATP concentrations or ventricular function after ischaemia–reperfusion (fig. 5). This is to be expected, as experimental[36] and clinical studies[64] suggest that immature hearts normally have decreased concentrations of 5'-nucleotidase compared with adult hearts. Deficiency of 5'-nucleotidase should ameliorate the loss of intracellular adenine nucleotides during reperfusion, so facilitating recovery after reperfusion by preserving the high-energy precursors able consequently to participate in salvage re-synthesis of ATP. Experimentally, 5'-nucleotidase activity may be related inversely to functional recovery after ischaemia–reperfusion,[36] but this has not been confirmed in humans.[64] This may be because of degradation of high-energy phosphates by alternative biosynthetic pathways not involving 5'-nucleotidase.

DEVELOPMENTAL CHANGES IN CONTRACTILE PROTEINS AND RESPONSE TO INJURY

Clinical studies have demonstrated significant postnatal increases in myocardial contractility.[2 23] This is related to an increase in the relative amount of contractile protein and delivery of Ca^{++} to the myofilaments. In addition, there are differences in kinase, myosin, actin and tropomyosin isoforms between the newborn and adult human, although the functional significance of this developmental change is unknown.[81] There do not appear to be any developmental variations in C-protein in the heart. However, developmental changes in troponin isoforms have been shown to be of functional importance. There are two troponin I isoforms, the relative proportion of the immature skeletal isoform decreasing with maturation. The switch to the adult cardiac isoform appears to be complete postnatally in humans.[81] There is considerable functional difference in the two troponin I isoforms such that the myofibrillar ATPase of the fetus and newborn has an increased sensitivity to Ca^{++} and desensitivity to acidosis.[10] In addition, expression of the four different troponin T isoforms differs with age, another reason why newborn myofibrils have enhanced Ca^{++} sensitivity compared with adults. Although some experimental work suggests that the decrease in contractile force in stunned myocardium is a result of a decrease in maximum calcium-activated force without desensitization of the myofilaments to Ca^{++},[39] other studies have demonstrated the converse.[74 101] It is probable that both mechanisms are involved to a greater or lesser degree. The reduction in sensitivity for Ca^{++}, secondary to myofilament injury occurring during reperfusion–reoxygenation, is probably a result of a reduced affinity of troponin C for Ca^{++}. This suggests that age-related changes may not affect the reduced affinity of troponin C for Ca^{++} induced by stunning, as troponin C is invariant throughout development. However, the altered Ca^{++} binding of troponin C may either be a direct result of reperfusion–reoxygenation injury or an indirect result of degradation of other regulatory thin filament proteins, such as troponin I and T.[74] The latter possibility increases potential developmental influences. The time course of recovery suggests that normal function returns only when irreversibly damaged protein is replaced. This hypothesis is consistent with observations that inotropic drugs that increase cytosolic Ca^{++} concentration during systole can enhance function in stunned myocardium to near normal levels.[32] The finding that maximal tension-generating capabilities of isolated myocytes can be unchanged while injured suggests that stunning has no significant effects on myosin, actin or crossbridge states.

DEVELOPMENTAL CHANGES IN CORONARY ENDOTHELIAL FUNCTION AND RESPONSE TO INJURY

Impairment of coronary vascular endothelial function induced by ischaemia–reperfusion is characterized by a reduced vasodilator response to endothelial stimulation of nitric oxide. Although hypothermia impairs release of nitric oxide from coronary endothelium, this appears to be a rapidly reversible phenomenon on rewarming.[30] Experimental work has suggested that immature hearts have better recovery of endothelial function compared with adult hearts after hypothermic ischaemia–reperfusion (fig. 6). Ischaemic hearts reperfused with leucocyte-depleted blood[95] or given monoclonal antibodies to leucocyte adhesion molecules[40] demonstrate significantly reduced endothelial reperfusion injury, suggesting that neutrophil activation is involved. Coronary vascular endothelial cells differ from myocytes in that their response to ischaemia–reperfusion is in complete contrast with their response to hypoxia–reoxygenation. The addition of a nitric oxide donor[83] or L-arginine[94] to cardioplegia, or post-CPB administration of nitroglycerin[56] have been shown to ameliorate reperfusion injury induced by coronary endothelial dysfunction. This is because during ischaemia, blood flow is stagnant and neutrophils become adherent and then "activated" during reperfusion. Nitric oxide inhibits neutrophil adherence to vascular endothelium and inhibits subsequent activation and oxygen free radical generation. Conversely, nitric oxide may accelerate reoxygenation damage when blood flow is high and neutrophil adherence unlikely.

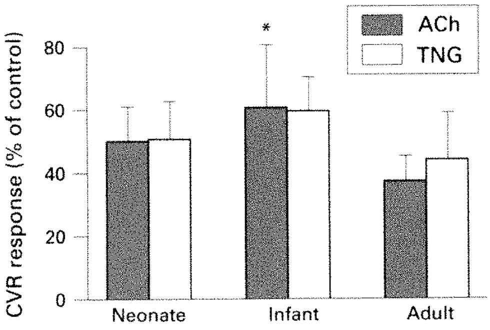

Figure 6 Isolated, blood perfused hearts from 2–7-day-old (neonate), 1-month-old (infant) and 1-yr-old (adult) sheep were subjected to 2 h of ischaemia at 15°C and given crystalloid cardioplegia every hour. Endothelial function was assessed by coronary vascular resistance (CVR) responses to the endothelium-dependent vasodilator acetylcholine (ACh) and the endothelium-independent vasodilator trinitroglycerin (TNG) and expressed as mean (SD) percentage of baseline values obtained before hypothermia. The ACh value for the infant group was significantly different from that of the adult group ($*P < 0.05$). Data from Hiramatsu and colleagues.[41]

Constitutive nitric oxide synthase activity is related to oxygen tension, and uncontrolled reoxygenation using a high arterial partial pressure of oxygen leads to excessive nitric oxide production. This excess of nitric oxide reacts with superoxide anion to generate highly toxic reactive oxygen intermediates that can cause lipid peroxidation and subsequent myocardial dysfunction. Experimental studies have shown that suppression of nitric oxide production during controlled reoxygenation can reduce endothelial and myocardial dysfunction.[46]

Part 2. Principles of prevention of myocardial stunning in the neonate

Determination of the optimal method of myocardial protection in the neonate has been the subject of much experimental research. However, the use of diverse mammalian species, each with different rates of development, may appear an unreliable basis to provide appropriate data. Moreover, many studies have relied on isolated heart preparations that fail to model non-coronary collateral flow, neurohormonal influences and the effects of cardiopulmonary bypass (CPB). Nevertheless, this experimental evidence, together with accumulating clinical experience, has provided useful guiding principles that are helping clinicians find safe, effective methods of enhancing myocardial protection for the neonate at risk of stunning. Most techniques of intraoperative myocardial protection rely on reducing myocardial oxygen demand which is determined primarily by electromechanical activity and secondarily by metabolic rate. Electromechanical work is minimized by potassium-induced diastolic arrest, and basal metabolic rate is reduced with hypothermia. However, the effects of hypothermia and cardioplegic arrest on myocardial oxygen consumption may differ in the neonate compared with the adult, and it would appear that for neonates, cardioplegic arrest may add little extra myocardial protection to that offered by hypothermia alone (fig. 7).[44 49 54 55] Thus profound hypothermic circulatory arrest, without the use of cardioplegia, remains a widely used method of combining myocardial protection with a bloodless and motionless surgical field. Non-neurological complications and haemodynamic profile are similar if low-flow CPB or circulatory arrest is used.[109] However, the higher incidence of neurological complications associated with circulatory arrest[12] has revived interest in strategies that allow perfusion to be maintained throughout surgery in even the smallest neonate. This has led to the development of specific cardioplegic techniques for neonates. In addition to the main preventative strategies of hypothermia and cardioplegia, other adjuvant techniques are under investigation.

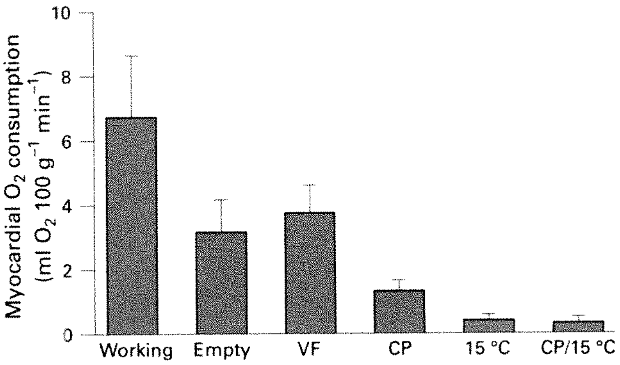

Figure 7 Mean (SD) myocardial oxygen (O_2) consumption (expressed in millilitre of O_2 per 100 g of ventricular tissue per minute) was measured in isolated neonatal piglet heart preparations when working, empty beating, fibrillating (VF), cardioplegic arrested at normothermia (CP), hypothermic (15°C) or cardioplegic arrested at 15°C. All values were significantly different except those obtained at 15°C ($P < 0.05$). Data from Jessen, Abd-Elfattah and Wechsler.[49]

HYPOTHERMIA

Myocardial temperature may be decreased using perfusion cooling or topical cooling, or both. Topical cooling can be achieved by bathing the heart surface with ice slush, although this method is ineffective at cooling the most vulnerable sub-endocardial regions and most paediatric cardiac surgeons use topical cooling only as an adjunct to perfusion-induced cooling. Cold cardioplegic solutions or CPB, or both, are very effective at cooling the heart and can be used in combination. It is comparatively easy in neonates to ensure that CPB-induced hypothermia produces temperature equilibration throughout all tissues of the body, as neonates have a higher proportion of vessel-rich tissues than adults. Whole body perfusion cooling allows low CPB flow rates or circulatory arrest, as tissue energy requirements are substantially reduced at low temperature. However, the temperature dependency of biochemical reactions is variable and hypothermia, therefore, can lead to derangement of intracellular homeostasis. In particular, the variable effect of low temperature on sarcolemmal[102] and SR[61] channels results in increased intracellular Ca^{++} concentration. Thus although hypothermia is believed to improve tolerance to ischaemia, intracellular Ca^{++} accumulation induced by hypothermia may lead to exacerbation of ischaemia–reperfusion injury. Experimental studies have indicated that hypothermic perfusion before ischaemia may attenuate functional recovery after reperfusion, but that this detrimental effect can be ameliorated by hypocalcaemic perfusion before[5] or during cardioplegic arrest.[13] One clinical study suggested that rapid myocardial cooling could result in significant damage and recommended "slow" cooling before induction of cardioplegic arrest.[112] However, more recent experimental studies have been unable to confirm that rapid cooling is more detrimental than slow cooling to the immature myocardium.[54,55] Furthermore, prolonged hypothermic CPB perfusion may itself be deleterious to the immature heart,[44,100] particularly if electromechanical activity is sustained.[107] In addition to intracellular Ca^{++} accumulation, prolonged hypothermic perfusion may be associated with hyperglycaemia and inhibition of mitochondrial function, which leads to metabolic derangement and decreased ATP production.[107] In clinical practice, perfusion cooling at a rate of 1°C min^{-1} is used as a compromise between restricting the duration of pre-arrest hypothermic perfusion and optimizing tissue temperature equilibration. Inter-species differences and use of different study end-points have complicated the identification of the optimal temperature for prolonged myocardial protection. A study of ATP metabolism and contractility in canine hearts subjected to either normothermic (37°C) or hypothermic (15°C) cardioplegic arrest found similar reductions in tissue ATP concentrations in each group.[99] However, hypothermic perfusion resulted in a threefold increase in adenosine and AMP concentrations compared with normothermic hearts, suggesting that hypothermia to 15°C may produce beneficial inhibition of nucleotide breakdown. Furthermore, myocardial function was not significantly different between the two groups, suggesting that hypothermia to 15 °C is not detrimental to myocardial function. It must be emphasized, however, that these relatively innocuous effects of hypothermia relate to arrested hearts; when electromechanical activity is maintained, hypothermic perfusion may cause myocardial injury.[107] In rabbits, there appears to be a biphasic relationship between the extent of protection and degree of hypothermia (fig. 8). Decreasing myocardial temperatures to less than approximately 20°C did not confer additional protection, but higher temperatures provoked rapid loss in protection.[57] In contrast, a study involving neonatal pigs found that time to ischaemic contracture and decline in ATP concentrations were significantly less in hearts maintained at 12°C compared with hearts at 19°C. Moreover, the protective effects of hypothermia were significantly reduced if pre-ischaemic ATP concentrations were low.[113] One clinical study has suggested that myocardial temperatures less than approximately 15°C may inhibit energy substrate production by anaerobic glycolysis to a greater degree than energy consumption.[53] In keeping with these findings, most centres using circulatory arrest techniques aim to maintain myocardial temperatures between 15 and 20°C throughout surgery. The period immediately after corrective surgery is undoubtedly crucial to ultimate recovery, as reperfusion–reoxygenation injury may be occurring at the same time as oxygen consumption is increasing, secondary to the increase in metabolic rate and initiation of reparative and electromechanical activity. Inevitably, it has been difficult to identify the relative importance of the effects of reperfusion, reoxygenation and rewarming on the immature heart. Experimental studies have shown that hypothermia-induced depression of myocardial function and depression of metabolic activity may persist during rewarming.[106,107] Moreover, rewarming from profound hypothermia can cause structural derangement of the sarcolemma, possibly caused by lipid peroxidation.[67] The standard rewarming rate of 1°C min^{-1} is a compromise between the time required for optimizing tissue temperature equilibration and keeping reperfusion of the non-working heart to a minimum.[59] None the less, clinical experience indicates that a significant increase in contractility occurs during the later stages of rewarming. Thus some prolongation of normothermic perfusion to the *working* heart may allow better myocardial recovery before the workload of the heart increases as a result of the increase in systemic vascular resistance after CPB.

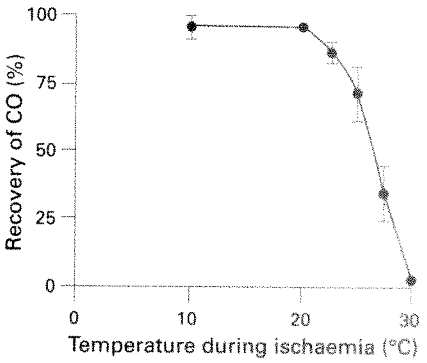

Figure 8 Isolated working heart preparations obtained from neonatal rabbits were perfused with oxygenated, buffered fluid for 20 min at 37°C before single infusion of crystalloid cardioplegia and ischaemic arrest at maintained temperatures of 10, 20.0, 22.5, 25.0, 27.5 or 30.0°C for 4 h. Cardiac output (CO) was measured after 60 min of working reperfusion and expressed as mean (SEM) percentage recovery compared with pre-ischaemia values. Data from Kempsford and Hearse.[57]

CARDIOPLEGIA

Although there is widespread use of cardioplegia in paediatric cardiac surgery, optimal temperature, composition and delivery pressure of the solution remain subjects of controversy. The main reason for using cardioplegia is to maintain the heart in diastolic arrest while the aorta is clamped and there is no coronary blood flow. In addition, the cardioplegic solution can be used to assist in the uniform cooling or warming of the arrested heart. However, if profound hypothermia is induced by CPB, the additional cooling effect of cardioplegia infusion on the myocardium may be relatively small. Moreover, experimental evidence suggests that solutions at temperatures <4°C may have detrimental effects, probably secondary to endothelial injury.[4] Clinical studies in adults suggest that use of warm cardioplegia to induce diastolic arrest or infusion again, or both, immediately before unclamping the aorta may reduce reperfusion–reoxygenation damage,[18] although this has not been confirmed in neonates. The cardioplegic solution usually contains a high concentration of K^+ (15–20 mmol $litre^{-1}$) that produces electromechanical arrest by reducing the resting membrane potential and inactivating the fast sodium channel in the sarcolemma. Return of electromechanical activity while the aorta is clamped, which increases the possibility of myocardial injury, is more likely to occur when myocardial temperatures are high or when non-coronary collateral flow results in washout of the high concentration of K^+ in the extracellular fluid. Thus in order to maintain diastolic arrest when myocardial temperature is greater than approximately 20°C, cardioplegic infusions may need to be given every 15–30 min. Experimental studies using isolated cell cultures have demonstrated age-related differences in the response of the myocyte to hyperkalaemia.[25, 71] In adults, hyperkalaemia produces a significant increase in cell volume and reduction in contractility that is not seen in myocytes from immature rabbits. This developmental difference may relate to calcium-induced myocyte injury, as hyperkalaemia-induced depolarization of immature myocytes does not result in as great an increase in intracellular Ca^{++} concentration as has been demonstrated in adults. The mechanism for this Ca^{++} influx during hyperkalaemia varies with age. In adults the primary entry route for the increase in cytosolic Ca^{++} is the sarcolemmal calcium channel, whereas in the immature myocyte it is the Na^+–Ca^{++} exchanger.[25] The SR has no influence on cytosolic Ca^{++} during hyperkalaemia at any age. The potential for hypothermia and hyperkalaemia to cause calcium influx has made the optimal Ca^{++} concentration of cardioplegia for the neonate a controversial topic.[70] Immature rabbit hearts receive maximum myocardial protection when the cardioplegic solution contains only Ca^{++} 0.3–0.4 mmol litre^{-1},[8] although neonatal piglet hearts appear to benefit from normocalcaemic solutions.[87] More recent work[13] may have helped resolve this issue. Myocardial protection appears to be independent of cardioplegic Ca^{++} concentration in normal neonatal piglet hearts. However, when a comparable group of piglets subjected to hypoxia–reoxygenation injury before cardioplegic arrest are given normocalcaemic blood cardioplegia, they demonstrated significantly reduced functional recovery and ATP concentrations after CPB compared with those given hypocalcaemic blood cardioplegia (fig. 9). In addition, the concentration of magnesium (Mg^{++}) in the cardioplegic solution has a significant influence on the extent of Ca^{++} influx induced by hyperkalaemia. Increasing concentrations of extracellular Mg^{++} can displace Ca^{++} from the glycocalyx, thus reducing the amount of extracellular Ca^{++} available for trans-sarcolemmal entry, whether by calcium channel or Na^+–Ca^{++} exchanger.[25] It follows that the optimum Ca^{++} concentration of cardioplegia for the neonate varies depending on the complex interaction between pre-injury hypoxia, duration of ischaemia, Mg^{++} concentration of the solution and myocardial temperature. Although the relative merits and demerits of blood and crystalloid cardioplegic solutions remain subjects of controversy, it appears that blood is becoming the preferred vehicle.[18] The main advantages of blood cardioplegia are its greater buffering and oxygen carrying capacities compared with crystalloid cardioplegia. Although there is a shift in the oxyhaemoglobin dissociation curve to the left secondary to hypothermia, oxygen unloading from cold blood cardioplegia is greater than that expected because of a compensating rightward shift induced by myocardial tissue acidosis, hypercapnia and rewarming.[43] The buffering capacity of blood cardioplegia is usually much greater than that of crystalloid cardioplegia because of the presence of the amino acid histidine, which has an imidazole group that can accept protons. The other potential advantages of blood cardioplegia, which include its beneficial oxygen free radical scavenging, rheological and oncotic properties, do not appear to be subject to developmental influences. The few experimental studies comparing multi-dose blood and crystalloid cardioplegic solutions in hypothermic, immature hearts have shown that the blood vehicle offers better myocardial protection.[24, 87] A single dose of crystalloid cardioplegic solution given at the onset of ischaemia may add to the protection offered by profound hypothermia,[80] but repeated doses appear to be of little further benefit or may even inhibit subsequent recovery of the immature heart.[68] This detrimental effect of multi-dose cardioplegia may be a result of the repeated alteration in H^+ ion gradient between the inside and outside of the cell, causing ions to move through the Na^+–H^+ exchanger during every infusion.[7] There has been concern that hyperkalaemic cardioplegia may induce endothelial cell injury, although high pressure delivery of the solution may be more to blame.[30] High infusion pressure can induce endothelial injury and although control of infusion pressure does not guarantee normal shear stress in the epicardial coronary artery, it is minimized at aortic root pressures of 90–120 mm Hg in the adult dog.[30] Similarly, a study using mature rats has shown that cardioplegia delivered at pressures of 75–105 mm Hg produced better functional and metabolic myocardial recovery than when cardioplegia delivery was at either higher or lower pressures (fig. 10).[48] Thus although there has been no confirmatory clinical evidence, it would seem advisable that in the human neonate, cardioplegia is infused at normal aortic root pressures, that is 60–80 mm Hg. Similarly, reducing coronary artery pressure during initial reperfusion may improve endothelial function[96] by limiting excessive nitric oxide production induced by shear stress.[46] Experimental studies have shown that amino acid enrichment of cardioplegic solutions improves both meta-

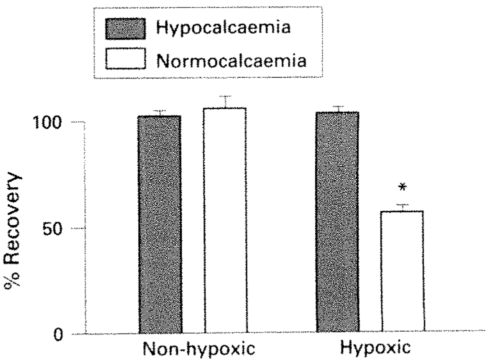

Figure 9 Neonatal piglets were placed on hyperoxaemic cardiopulmonary bypass (CPB) and subjected to either multi-dose normocalcaemic or hypocalcaemic blood cardioplegic arrest for 70 min. Half the piglets had previously undergone ventilation for 60 min with an inspired oxygen concentration of 8% to render them hypoxic. Myocardial function was assessed 30 min after CPB and expressed as mean (SEM) percentage of pre-CPB values. Both hypocalcaemic and normocalcaemic multi-dose blood cardioplegic solutions allowed complete recovery in the non-hypoxic group. In contrast, the group who had been exposed to acute hypoxia–reoxygenation injury before cardioplegic arrest demonstrated significantly reduced recovery when normocalcaemic blood cardioplegia was used ($*P < 0.05$). Adapted from Bolling and colleagues,[13] with permission.

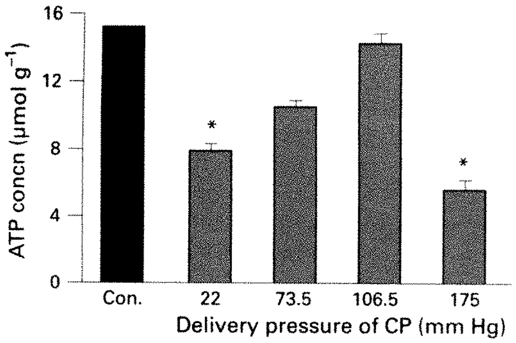

Figure 10 Isolated heart preparations from adult rats were perfused with oxygenated buffered solution before multi-dose crystalloid cardioplegic arrest for 210 min at 12°C. Adenosine triphosphate (ATP) concentration in each heart was determined after 60 min of reperfusion. Each group of hearts had cardioplegia (CP) delivered at a different pressure. Mean (SEM) ATP concentrations in hearts receiving CP at pressures of 22 and 175 mm Hg were significantly lower than pre-ischaemia control values (Con.) ($*P < 0.05$). Adapted from Irtun and Sirlie,[48] with permission.

bolic and functional recovery of ischaemic immature myocardium.[86, 108] In addition to replenishing myocyte energy substrates, glutamate and aspartate inhibit L-arginine transport and subsequent production of reactive oxygen intermediates, hence reducing reoxygenation injury.[46] Experimental studies have shown that fumarate may offer metabolic support without causing the systemic vasodilatation that characterizes glutamate administration.[86] Fumarate, a Krebs' cycle intermediate, can be reduced to succinate with the concomitant oxidation of NADH, resulting in ATP production, even under hypothermic, ischaemic or hypoxic conditions. Furthermore, in addition to its metabolic effects, fumarate stimulates mitochondrial uptake of Ca^{++} under anoxic conditions and may also act as a free radical scavenger. Other cardioplegic additives that have produced encouraging amelioration of stunning injury to the myocyte or endothelium, or both, include nitric oxide donors, L-arginine, adenosine and potassium channel blockers. It is important to differentiate between reperfusion injury and reoxygenation injury when reviewing the use of agents that affect nitric oxide production (see also DEVELOPMENTAL CHANGES IN CORONARY ENDOTHELIAL FUNCTION AND RESPONSE TO INJURY above). Reperfusion injury may be reduced by using agents that enhance nitric oxide production,[83] whereas reoxygenation injury can be reduced by using agents that suppress nitric oxide production.[46] Alternatively, reoxygenation injury can be minimized by delaying and controlling reoxygenation (see CONTROLLED REOXYGENATION below). Adenosine and ATP-sensitive potassium channel blockers inhibit hyperkalaemic-induced Ca^{++} influx into the myocyte,[50] and therefore may not be particularly beneficial in neonates. However, both adenosine and ATP-sensitive potassium channels have been implicated in the mechanism of preconditioning (see PRECONDITIONING next).

PRECONDITIONING

Repeated ischaemic episodes would be expected to have a cumulative adverse effect on myocardial function, but instead of becoming sensitized, the heart exhibits a marked resistance to myocardial injury after subsequent prolonged ischaemia. This capacity for endogenous protection, termed preconditioning, can also be initiated by other stimuli such as hypoxia.[22] When preconditioned myocardium is subjected to sustained ischaemia, ATP use and anaerobic glycolysis occur at much slower rates than normal, and the duration of ischaemia that can be tolerated before irreversible injury to the myocyte occurs is greatly extended. The mechanism for preconditioning is unknown, but must involve the release of endogenous substances from the ischaemic myocardium because regional preconditioning can protect remote non-preconditioned tissue. Current research has implicated adenosine A1 and α_1 receptors, inhibitory G proteins, ATP-sensitive potassium channels and protein kinase C in this phenomenon.[22, 97] Preconditioning requires a minimum duration of initiating insult and its protective effects last only a few hours. Early studies established that preconditioning could limit infarct size and reduce reperfusion injury-induced ventricular arrhythmias. More recently, experimental studies have demonstrated that preconditioning can enhance the recovery of stunned human myocardium[21] and animal work has demonstrated that preconditioning preserves normal mitochondrial function and facilitation of glycolysis during reperfusion.[115] Preconditioning has been demonstrated in adults undergoing coronary artery surgery,[117] although the efficacy of this phenomenon in humans remains a subject of debate.[88] More clinical studies in adults undergoing cardiac surgery are required before the therapeutic potentials for paediatric practice can be explored.

CONTROLLED REOXYGENATION

Experimental studies have demonstrated that hyperoxic reoxygenation of previously hypoxic immature piglet hearts causes oxidant injury, reduction in anti-oxidant reserve capacity and a decrease in myocardial contractility.[78] The extent of oxidant injury secondary to reoxygenation appears to correlate with nitric oxide production. Suppression of excessive nitric oxide production by controlling reoxygenation and supplementing blood cardioplegia with glutamate–aspartate increases functional recovery.[46] Experimental studies have shown that reducing oxygen tension to approximately 100 mm Hg during reoxygenation avoids oxidant injury, retains normal anti-oxidant reserve and improves myocardial functional recovery (fig. 11). These data suggest that reoxygenation injury can be minimized by initiating CPB at the ambient oxygen tension of the hypoxic neonate and delaying controlled reoxygenation until after cardioplegic arrest. Immature hearts subjected to reoxygenation injury before cardioplegic arrest have increased reperfusion injury and decreased functional recovery compared with hearts not subjected to reoxygenation before arrest, even if blood cardioplegia is used. Supplementation of the cardioplegic solution or the CPB prime with antioxidants,[77] or strategies designed to reduce nitric oxide production may reverse this increase in reperfusion injury.[46] A further increase in recovery can be produced if reoxygenation injury can be minimized by delaying reoxygenation until cardioplegic arrest is initiated.[75]

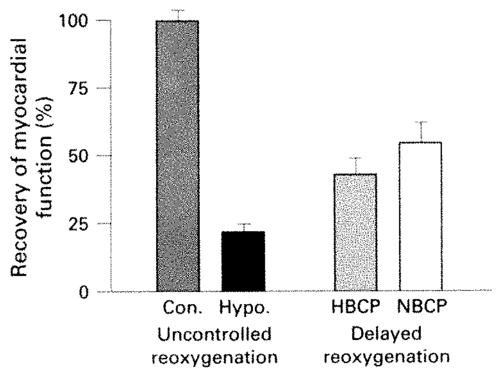

Figure 11 In immature piglets on cardiopulmonary bypass (CPB), the aorta was clamped for 30 min while given multi-dose blood cardioplegia (BCP) and reperfused for 25 min before measurements of myocardial function were obtained 30 min after CPB. The control group (Con.) were normoxaemic before being placed on hyperoxaemic (Po_2 = 53.3 kPa) CPB and given hyperoxaemic BCP (Po_2= 53.3 kPa). The other group of piglets had been made hypoxic (Hypo.) by lowering their inspired oxygen concentration to 7% for 120 min before CPB. They were then subjected to either uncontrolled reoxygenation (placed on hyperoxaemic CPB and then given hyperoxaemic BCP) or reoxygenation was delayed until the aorta was clamped and then received either hyperoxaemic (HBCP) or normoxaemic BCP (NBCP). After CPB, myocardial function was compared with pre-CPB values and expressed as mean (SEM) percentage recovery. Previously hypoxic piglets achieved their best recovery when reoxygenation was delayed until after BCP arrest and on receiving normoxaemic BCP (NBCP). Adapted from Ihnken and colleagues,[46] with permission.

OTHER ADJUVANT THERAPY

An infusion of glucose–potassium–insulin given before stunning may promote glucose uptake by the myocardium and increase intracellular energy substrate concentrations.[103] In addition, insulin reduces the concentration of free fatty acids and promotes myocardial glycogen synthesis. Moreover, Krebs' cycle carbohydrate metabolism after reperfusion is improved, as insulin stimulates the activity of pyruvate dehydrogenase, which is normally inactivated during ischaemia. Clinical studies in adults have shown that the haemodynamic effects of catecholamines may be increased by using high-dose insulin to shift myocardial metabolism from free fatty acid oxidation to carbohydrate metabolism.[104] However, the practical difficulties of maintaining normoglycaemia while giving insulin throughout the perioperative period continue to make this therapy relatively unpopular. Adults given infusions of glutamate during stunning have demonstrated improved haemodynamic performance and metabolic profile.[103] Glutamate and aspartate enhance glycolysis, improve lactate clearance, replenish Krebs' cycle intermediates and stimulate alternative anaerobic pathways for regeneration of ATP during ischaemia–reperfusion. Although these potential benefits explain why preoperative infusions of certain amino acids have been advocated, glutamate causes pronounced dose-related systemic vasodilatation, and it is usually given only as an additive to the cardioplegic solution or CPB prime.[76 103]

Conclusions

As primary corrective surgery in the neonate becomes more common, more complex and more time consuming, the search continues for therapeutic strategies that will extend the safe duration of induced myocardial ischaemia. Although the use of animal models to investigate the influence of age on myocardial stunning is understandable and necessary, it also implies that such work should be subject to cautious interpretation before extrapolation of their conclusions to the human neonate. Nevertheless, the information engendered from many of these studies has suggested modifications in our management of neonates undergoing cardiac surgery that have subsequently proved useful and efficacious. Now that specific biochemical markers of myocardial damage that can be sampled from coronary sinus outflow have been identified, clinical studies should be able to help further refine and optimize our currently available methods of myocardial protection for this challenging group of patients.

SHORT COMMUNICATION

Neuromuscular monitoring by intensive care nurses: comparison of acceleromyography and tactile assessment

R. Greer, N. J. N. Harper and A. J. Pearson

Summary

We have compared tactile assessment of the train-of-four (TOF) count and TOF ratio by nursing staff, with measurements made by a new acceleromyographic monitor, the TOF-Watch. We assessed neuromuscular block in 30 sedated intensive care patients receiving a continuous infusion of atracurium. Five nurses made a tactile assessment of neuromuscular block in each patient within a 5-min period. Each assessment was paired with a blinded TOF-Watch measurement. The nurses were accurate in assessing twitch count in 55% of measurements and they tended to overestimate the degree of block using tactile assessment of TOF ratio. (*Br. J. Anaesth.* 1998; **80**: 384–385)

Keywords: Intensive care; monitoring, neuromuscular function; neuromuscular block, measurement of response; equipment, acceleromyograph

The use of neuromuscular blocking drugs in the intensive care unit is commonplace. It is important to monitor neuromuscular function in the critically ill because the action of these drugs varies widely in this population.[1] Tactile assessment of the train-of-four (TOF) is used commonly in anaesthetic practice to assess the degree of block, but there are few published data on tactile assessment of neuromuscular block in the intensive care unit. The majority of routine monitoring of vital signs in the intensive care unit is performed by nurses. Our aim was to compare the accuracy of nurse assessment of TOF responses with acceleromyography, which is a reproducible method of measurement.

Acceleromyography uses the principle that acceleration of a contracting muscle is proportional to the force of contraction (Newton's second law). In a previous study it was demonstrated that a similar acceleromyography device gave results comparable with those of a standard mechanometric device (Myograph 2000) but there was greater variation in responses to acceleromyography.[2] The TOF-Watch (Organon teknika) is an electromyographic device. It comprises a standard nerve stimulator and a small piezoelectric acceleration transducer that is attached to the thumb. The TOF-Watch enumerates the TOF ratio and TOF count on a liquid crystal display.

Methods and results

We investigated 30 stable, sedated adult patients receiving an infusion of atracurium in our intensive care unit. ECG-type electrodes were placed over the ulnar nerve of both wrists. The TOF-Watch was used to obtain acceleromyographic measurements of neuromuscular block at one thumb (adductor pollicis). The stimulating leads of the TOF-Watch were then disconnected and reconnected to similar electrodes on the contralateral wrist when tactile assessment was made. In this way the same nerve stimulator was used for tactile and acceleromyographic measurements at different wrists. We used two wrists to avoid displacement of the sensitive acceleration transducer between measurements: a small change in position could have affected the results. The same stimulating current was used at both wrists (60 mA). We ensured that the electrode position was identical at both wrists and we assigned at random the dominant and non-dominant hands for measurement. The nurse caring for the patient (nurse A) made a tactile TOF assessment and then a TOF-Watch measurement. Four subsequent assessments were made by four different nurses who were blinded to the TOF-Watch result. At the same time as each tactile assessment, nurse A made a TOF-Watch measurement on the patient's other hand. Each of the four nurses stated the number of twitches she could feel in response to a TOF stimulus and if four were palpable she declared a TOF ratio. One minute elapsed between measurements. In this way we obtained five pairs of data for each patient. The nurses were given standard instructions in the simple theory and relevance of neuromuscular function; however, they were not given practical experience in the technique before commencement of the study.

The nurses estimated correctly the twitch count in 80 assessments (54%); they overestimated the count in 38 assessments (25.3%) and underestimated it in 31 (20.6%). Seventeen percent of assessments were inaccurate by two twitches (fig. 1). A Bland and Altman plot[3] demonstrated that nurses tended to overestimate the TOF ratio by a small amount. There was also greater variability among the nursing assessment of the TOF ratio than among the TOF-Watch measurements. No learning effect could be demonstrated by comparing the assessments of the first 10 patients and the last 10.

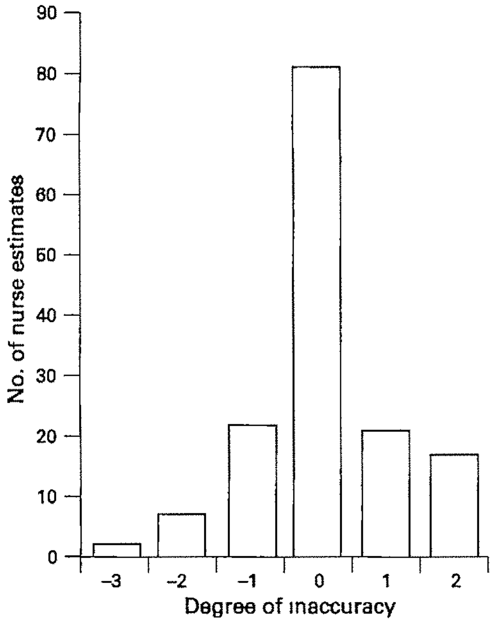

Figure 1 Degree of inaccuracy with which ICU nurses estimated the number of train-of-four responses. A degree of inaccuracy of −1, for example, indicates that the nurses were able to feel one fewer response than the number measured by the TOF-Watch.

Comment

The use of neuromuscular blocking drugs in the intensive care unit is common. However, monitoring of neuromuscular function in the intensive care unit is not performed routinely. It is important to assess the degree of block in critically ill patients because the action of these drugs varies widely in this population. Changes in the pharmacokinetics and pharmacodynamics of neuromuscular blocking drugs may occur and these patients may demonstrate increased or decreased sensitivity to these agents. Differing degrees of block are required depending on the clinical indication for the use of neuromuscular blocking agents in the intensive care unit.

Acceleromyography has been described as a method of measurement of neuromuscular block during anaesthesia.[4] Acceleromyographic and mechanomyographic measurements of TOF responses compare well during stable neuromuscular block. Our study of tactile assessment of TOF count found that the nurses were inaccurate in 45% of measurements and the degree of inaccuracy was two twitches or more in 17% of cases. Underestimation of twitch count leads to overestimation of the level of block, which may mislead doctors and nurses into reducing the rate of infusion of atracurium. A patient in whom a deep level of block is required to avoid an increase in intracranial pressure or to improve thoracic compliance may be put at risk by this course of events.

Measurement of TOF ratio is an important method of assessing recovery from neuromuscular block. It has been shown that tactile assessment of TOF ratio by medical staff is inaccurate at low levels of block.[5] Our results demonstrated that nursing staff tended to overestimate TOF ratio. There was also greater variability in the assessments by the nursing staff. Full recovery from neuromuscular block is important when it is necessary to make neurological or respiratory assessments after a period of block. Underestimation of the degree of block may lead to inaccurate patient assessment and inappropriate changes in therapy.

We suggest that acceleromyography is a useful tool in the intensive care unit. In particular, the TOF-Watch appears to be an appropriate neuromuscular monitor in this setting. The accuracy of tactile assessment of TOF twitch count and TOF ratio by nursing staff may not be a sufficient basis on which to make decisions on clinical management in the intensive care unit.

CASE REPORT

Accelerated recovery and disposition from rocuronium in an end-stage renal failure patient on chronic anticonvulsant therapy with sodium valproate and primidone

J. J. DRIESSEN, E. N. ROBERTSON, L. H. D. J. BOOIJ AND T. B. VREE

Summary

An end-stage renal failure patient, receiving chronic treatment with the anticonvulsants, sodium valproate and primidone, showed accelerated recovery with enhanced elimination ($T_{1/2}^{z}$ = 52 min) and clearance(Cl = 14.4 ml min^{-1} kg^{-1}) of rocuronium. The pharmacokinetic and pharmacodynamic effects of rocuronium in this patient are compared with those published for healthy and renal failure patients. Increased hepatic binding of rocuronium rather than metabolism is suggested as the possible cause of this effect. (*Br. J. Anaesth.* 1998; **80**: 386–388)

Keywords: anticonvulsants; kidney, failure; neuromuscular block, rocuronium; pharmacokinetics, rocuronium

It is well documented that patients treated chronically with anticonvulsant drugs such as phenytoin or carbamazepine are resistant to the effects of non-depolarizing neuromuscular blocking drugs.[1–5] Larger doses of neuromuscular blocking agents are required to produce a given degree of neuromuscular block and recovery from paralysis is faster. We report the case of an end-stage renal failure patient, receiving chronic treatment with the anticonvulsants, sodium valproate and primidone, who showed marked resistance to neuromuscular block, with enhanced elimination and clearance of rocuronium.

Case report

A 40-yr-old male (1.96 m, 69 kg) was undergoing placement of a peritoneal dialysis catheter. The patient suffered from end-stage renal failure caused by chronic glomerulonephritis and had been on haemodialysis for 2 yr. His daily urine output was approximately 100 ml and creatinine clearance <5 ml min^{-1}. Because of hypertension, mild left ventricular hypertrophy was present. After meningitis in early childhood, he had developed epileptic seizures. With his present medication, he had experienced no seizures since 1983. The patient had given written informed consent to participate in a study into the pharmacokinetics and pharmacodynamics of rocuronium 0.6 mg kg^{-1} in patients with renal failure, but the investigators were unaware of his antiepileptic therapy which would have excluded him from the study.

Haemodialysis was performed 24 h before surgery. Preoperative laboratory investigations included: haemoglobin 5.4 mmol litre^{-1}, serum creatinine 549 µmol litre^{-1}, serum urea 15.7 µmol litre^{-1}, serum albumin 34 g litre^{-1}, total serum protein 63 g litre^{-1}, serum ALAT/GPT 9 iu litre^{-1}, serum ASAT/GOT 15 iu litre^{-1} and potassium 4.8 mmol litre^{-1}.

His routine medication was: metoprolol 200 mg twice daily, minoxidil 10 mg twice daily, primidone 250 mg twice daily, sodium valproate 300 mg four times daily and calcium carbonate 500 mg five times daily. I.v. flucloxacillin 1 g, three times daily was given in the perioperative period as antibiotic prophylaxis.

The patient was premedicated with paracetamol 1 g and oxazepam 10 mg orally, 1 h before surgery. Before surgery, systolic arterial pressure was 150/80 mmHg with a heart rate of 72 beat min^{-1}. General anaesthesia was induced with fentanyl 0.1 mg and propofol 2 mg kg^{-1} via an i.v. infusion, and was maintained with continuous infusion of propofol 6–10 mg kg^{-1} h^{-1}, with supplementary bolus doses of fentanyl 0.1 mg as required. When the patient was asleep, neuromuscular function was monitored using transcutaneous supramaximal square wave stimuli of 0.2 ms delivered at 0.1 Hz with surface electrodes over the ulnar nerve at the wrist. Muscle contraction of the adductor pollicis was measured mechanomyographically with a Grass FT-03 force displacement transducer. After stabilization of the control twitch response for 5 min, rocuronium 42 mg (0.6 mg kg^{-1}) was administered as a fast i.v. bolus before tracheal intubation. Thereafter the patient's lungs were ventilated with 40% oxygen in nitrous oxide to achieve an end-tidal carbon dioxide partial pressure of 4–4.7 kPa. After the single twitch response recovered to 25%, train-of-four (TOF) stimuli were used every 12 s. Onset time (time to maximum twitch depression) time to recovery of the single twitch response to 25% and time to recovery of the TOF ratio to 0.7 were recorded. The time from injection of blocker until the first twitch of the TOF reached 75% recovery was also recorded.

Venous blood samples (4 ml) for measurement of rocuronium concentrations were obtained from the contralateral arm before and 2, 4, 7, 10, 15, 20, 30,

$T_{1/2}^{\gamma}$ (min)	52	104 (41)	91 (21)	97 (26.4)
MRT (min)	17	97 (49)	—	58 (9.6)

120, 180, 240 and 360 min after the bolus dose of rocuronium. Blood samples were anticoagulated with heparin, iced and centrifuged within 1 h of collection. Plasma was mixed with 0.2 ml of sodium dihydrogen phosphate 0.02 mol $litre^{-1}$ for every 1 ml of plasma, and stored at −30 °C until analysis by high pressure liquid chromatography (HPLC).

Analysis of rocuronium and the metabolites 17-desacetyl-rocuronium and 16-N-desallyl-rocuronium was performed according to the HPLC method of Kleef and colleagues.[6] Intra-day variability of rocuronium in plasma was 5.7% (cv) at 10 ng ml^{-1} and 0.82% at 100 ng ml^{-1}; inter-day variability was 15.2% and 15.8%, respectively. The accuracy of the assay in plasma was 97.0% at 10 ng ml^{-1} and 96.5% at 100 ng ml^{-1}.

Pharmacokinetic variables were calculated from the fitted plasma concentration–time curve after i.v. administration ($r^2 > 0.98$) according to a three-compartment model using the MW/Pharm computer package (Mediware, Groningen, The Netherlands).[7] Elimination half-life ($T_{1/2}$) values were calculated from ln2/β, where β is calculated by log-linear regression analysis of the terminal log-linear phase. $AUC_{0-\infty}$ (area under the plasma concentration–time curve) was calculated using the linear trapezoidal rule, with t being extrapolated to infinity. Total body clearance (Cl) is described as Cl = dose/$AUC_{0-\infty}$. V^{ss}, the volume of distribution at steady state, = $Cl \times$ MRT. $Cl = V^{ss} \times k_{el} = V^{ss} \times 0.693/T_{1/2}^{\gamma}$. Mean residence time (MRT) = $AUMC_{0-\infty}/AUC_{0-\infty}$, where $AUMC_{0-\infty}$ is the area under the moment curve from zero to infinity.

Table 1 shows the main pharmacodynamic and pharmacokinetic variables after rocuronium 0.6 mg kg^{-1} in our patient who was receiving primidone and sodium valproate, compared with published data in control renal failure and healthy patients. Onset time in our patient was 150 s and maximal twitch depression 99%. Figure 1 shows the plasma concentration–time curve of rocuronium in this patient. Total body clearance of rocuronium was 14.4 ml min^{-1} kg^{-1} and the terminal plasma elimination half-life was 52 min. The volume of distribution at steady state in our patient approximated the mean values in the reported studies.

The estimated plasma concentrations of rocuronium in this patient at TOF ratios of 0.7 and 0.9 were 0.85 mg $litre^{-1}$ and 0.58 mg $litre^{-1}$, respectively. The EC_{50} was calculated to be 2 mg $litre^{-1}$. No metabolites of rocuronium were detectable in plasma.

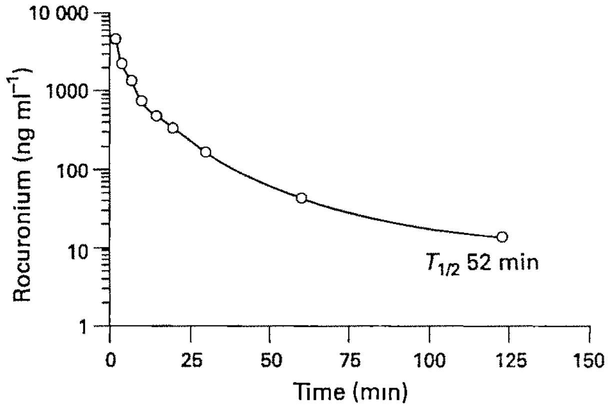

Figure 1 Plasma concentration–time curve (semi-log plot) after administration of rocuronium 0.6 mg kg^{-1} (42 mg) i.v. to a patient with end-stage renal failure receiving chronic anticonvulsant therapy with primidone and valproate No metabolites of rocuronium were measurable. Plasma concentrations of rocuronium at 180, 240 and 360 min were below the limit of quantitation of 10 ng ml^{-1}. $T_{1/2}$ = Terminal plasma elimination half-life (52 min)

Discussion

The clinical duration and recovery of rocuronium 0.6 mg kg^{-1} in our renal failure patient were markedly shorter than in the renal failure patients reported in two previous studies[8 9] or in healthy patients.[8] Clearance of rocuronium in our patient was faster and elimination half-life was shorter than in healthy patients.

A comparable case of decreased duration of action of rocuronium in a renal failure patient receiving chronic therapy with phenytoin has been reported.[9] In that patient, a greatly increased clearance of rocuronium was also found, which could in part be explained by the fact that the patient was still able to produce urine. The authors suggested hepatic enzyme induction by phenytoin as the likely mechanism of the interaction with rocuronium. Loan and collegues[10] also found reduced duration of action of rocuronium 0.6 mg kg^{-1} in patients receiving carbamazepine alone or in combination with other anticonvulsants.

For the observed resistance to non-depolarizing neuromuscular blocking drugs in patients receiving long-term treatment with phenytoin and carbamazepine, three possible mechanisms are reported: (1) increased hepatic metabolism and clearance by enzyme induction[1 9]; metabolites must be included in the overall analysis; (2) increase in protein binding which results in a decreased free fraction of drug to interact with the acetylcholine (ACh) receptor[11 12]; and (3) decreased ACh receptor sensitivity with subsequent up-regulation of the ACh receptor.[11 12]

Our patient was receiving chronic therapy with two other anticonvulsant drugs for which the interaction with neuromuscular blocking drugs is less well studied. Primidone is a prodrug; it is converted to phenobarbital which produces the antiepileptic effects. Primidone (phenobarbital) strongly induces the activity of drug metabolizing enzymes.[13] This is compatible with the high clearance and short elimination half-life of rocuronium in our patient. The elimination pathways of rocuronium remain uncertain, but hepatobiliary elimination is thought to be most important; only 10–30% of an injected dose of rocuronium is eliminated via the kidney.[1] The main metabolic pathway of rocuronium is esterase hydrolysis to 17-desacetylrocuronium. In this patient, plasma concentrations of metabolites were below the limit of quantitation. Thus it appears that rapid elimination and high clearance are unlikely to be caused by increased esterase or enzyme activity. The metabolites 17-desacetylrocuronium or 17-hydroxyrocuronium could be immediately excreted renally or conjugated with glucuronic acid and then excreted. However, this is also unlikely in our patient, as he had renal failure. A similar line of reasoning can be followed for the vecuronium–carbamazepine interaction because vecuronium shows comparable metabolic pathways to rocuronium (3-OH- and 17-OH-vecuronium); therefore, metabolites must be included in the overall analysis to detect increased metabolic elimination.

The actions of atracurium and mivacurium, neuromuscular blocking drugs which are eliminated mainly by plasma esterase and Hofmann degradation, are not affected by co-medication with phenytoin or carbamazepine.[14] However, recovery after doxacurium was twice as fast in patients receiving carbamazepine and phenytoin compared with a control group.[14] Thus vecuronium–rocuronium metabolism must differ from that of atracurium and mivacurium. Enzyme induction is followed by increased liver size and increased liver blood flow. If most of a dose of rocuronium is tightly/covalently bound to this increased number of liver receptor sites, then the apparent increased elimination, without metabolism, may explain the pharmacokinetic variables found in this patient.[15] When these liver binding sites are saturated, for example after long-term infusion in the ICU, then renal excretion becomes more important in the elimination of rocuronium in a similar way as that demonstrated for pancuronium.[16]

Sodium valproate is not an enzyme inducer but its addition to primidone increases serum concentrations of phenobarbital.[13] In contrast, valproic acid may cause up-regulation of the ACh receptor as acute administration in animals causes partial neuromuscular block and potentiates the effects of neuromuscular blocking drugs.[11] In this patient, however, the EC_{50} of rocuronium and plasma concentrations at TOF ratios of 0.7 and 0.9 were within the normal range.[8]

As the clinical relevance and mechanism of the interaction of sodium valproate and primidone with neuromuscular blockers remains unclear, further clinical and experimental study is necessary.

Acknowledgement

The authors thank Organon Teknika, Clinical Development Department, for their support in the analysis of plasma samples and for giving permission for publication of this patient who was eliminated from the original pharmacokinetic study in renal failure patients.

COMMENTARY

Multicentre evaluation of ryanodine contracture testing in malignant hyperthermia

P. M. Hopkins, E. Hartung, F. Wappler and the European Malignant Hyperthermia Group†

Summary

A common protocol for *in vitro* contracture testing using the plant alkaloid ryanodine has been used by the European Malignant Hyperthermia Group since 1993. This protocol describes a test using 1 µmol/litre of high purity ryanodine (98%) added as a single bolus dose. The main aim of this study was to compare the results obtained with this test between laboratories with a view to assessing the validity of adopting common diagnostic end-points for use in future collaborative studies. In order to do this it was first necessary to determine the optimum cut-off values of the end-points for discriminating between patients diagnosed as susceptible or not to malignant hyperthermia. The end-points under evaluation were expressed in terms of time after application of ryanodine at which a certain degree of contracture develops. In this study, four end-points were investigated: time to initial contracture development (0t); time to development of a 10-mN contracture (10t); time from addition of ryanodine to when baseline tension exceeds pre-drug tension (0tp); and time for contracture to reach 10 mN above pre-drug baseline tension (10tp). This protocol was developed initially and used by three investigating centres and the initial assessment of the end-points and their discriminatory ability was made using the first 100 patients from each of centres 1 and 2, and the first 90 patients from centre No. 3. Optimal cut-off values for each of the end-points were determined using logistic regression analysis. Discriminatory ability was improved by combining the 0t and 10t end-points ($P < 0.05$) but not significantly by combining the 0tp and 10tp end-points. Both methods of categorization were highly sensitive and specific compared with the current standard diagnostic tests. Results from eight additional diagnostic centres which have used the ryanodine contracture test more recently, while indicating that susceptible and normal individuals can be distinguished within a single laboratory, produced a level of variability between testing centres for the ryanodine contracture test that is incompatible with the use of common cut-off values. Possible causes for this variability between laboratories are discussed. (*Br. J. Anaesth.* 1998; **80**: 389–394)

Keywords. malignant hyperthermia; receptors, ryanodine; muscle skeletal, contractility

For more than 25 yr, diagnosis of malignant hyperthermia (MH) susceptibility has been achieved successfully with *in vitro* pharmacological tests on excised muscle strips using separate application of halothane[1] and caffeine.[2] After the recent revolution in the technology of molecular biological techniques, a real possibility has arisen of less invasive DNA-based diagnosis of MH susceptibility. There has been significant progress towards this aim but because of the complexity of the molecular genetics of MH, much more work needs to be done in this area before such a test could be considered reliable enough for safe clinical application.[3] The power of the molecular genetic studies, however, could be increased by improving the specificity of *in vitro* contracture test diagnosis. According to the protocol of the European Malignant Hyperthermia Group for laboratory diagnosis of MH,[4 5] individuals are classified as MH susceptible (MHS) if the muscle has abnormal *in vitro* responses to both halothane and caffeine; they are classified as MH normal (MHN) if their muscle has normal responses to both halothane and caffeine tests; if they respond abnormally to only one of halothane or caffeine they are classified as MH equivocal (MHE). For clinical purposes MHE patients are treated as susceptible to MH, as when there is any doubt over diagnosis the safest course of action is to avoid triggering drugs. It is generally accepted that the MHE group of patients includes some individuals who do not have a genetic predisposition to the disorder.

Ryanodine, a plant alkaloid that was used formerly as an insecticide, produces time- and concentration-dependent contracture of skeletal muscle *in vitro*. Its toxicity is caused by an avid affinity for reticulum calcium release channels[6] which have been subsequently termed ryanodine receptors by pharmacolo-

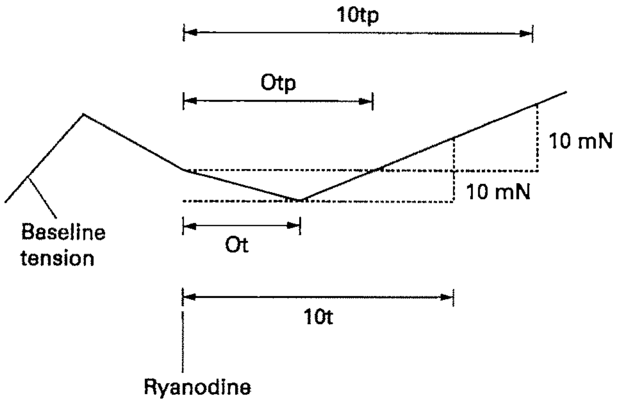

Figure 1 Diagrammatic illustration of the recording from a ryanodine contracture test to show determination of the four end-points evaluated in this study. Measures of early contracture development are time from addition of ryanodine to the first increase in baseline tension (Ot) and time from addition of ryanodine for baseline tension to return to pre-drug tension (Otp). Measures of late contracture development are time from addition of ryanodine to the development of a contracture of 10 mN above the minimum tension (10t) and time from addition of ryanodine to the development of a contracture of 10 mN above pre-drug tension (10tp).

gists. It was demonstrated that in muscle from pigs with porcine stress syndrome, a disorder similar to human MH, there was increased affinity of ryanodine to skeletal muscle calcium release channels compared with channels from muscle of normal pigs.[7] It was suggested subsequently that an *in vitro* contracture test with ryanodine might prove specific for human MH.[8–11] Although absolute sensitivity and specificity has not been achieved with ryanodine contracture testing, it seems likely that the addition of a ryanodine contracture test to the standard halothane and caffeine contracture tests could reduce the number of equivocal results.[12 13] More recently, Hopkins and colleagues[14] have shown that the addition of a ryanodine contracture test improves statistical modelling of contracture test data in order to predict the likelihood of patients being truly susceptible to MH, as would be beneficial for quantitative genetic analyses.

We have evaluated the degree of variability of results obtained with ryanodine contracture testing between laboratories of the European MH Group as a prerequisite to the use of such results in collaborative genetic and other studies. While it is not feasible to establish absolute reproducibility between laboratories because of the impossibility of transporting multiple specimens from single individuals across Europe within the few hours that the muscle remains viable, useful comparisons can be made between different centres by relating results of ryanodine contracture testing to those of the already well standardized caffeine and halothane tests. In the absence of previously agreed end-points for the ryanodine contracture test with which to make comparisons between the 11 centres participating in the study, it was first necessary to establish these and assess how well their use would discriminate between MHS and MHN.

Methods

RYANODINE CONTRACTURE TEST

Muscle bundles (20–30 mm × 2–3 mm × 2–3 mm) were excised from the vastus muscle under regional or trigger-free general anaesthesia. They were maintained in a modified Krebs solution containing (mmol litre^{-1}): NaCl 118.1, KCl 3.4, $MgSO_4$ 0.8, KH_2PO_4 1.2, $NaHCO_3$ 25.0, $CaCl_2$ 2.5 and glucose 11.1 at room temperature and gassed with 95% oxygen–5% carbon dioxide until testing. For contracture testing each muscle bundle was fixed at one end in a tissue bath with the free end of the bundle suspended by a silk suture from a force transducer. The tissue bath contained Krebs solution at 37 °C and was bubbled with 95% oxygen–5% carbon dioxide. The muscle bundle was pre-tensioned and subjected to electrical field stimulation to demonstrate viability: muscle bundles that did not respond to electrical stimulation with a twitch of >10 mN were considered to be non-viable and discarded. After a 10-min equilibration period, ryanodine 1 μmol litre^{-1} (98% pure, Calbiochem, La Jolla, CA, USA) was added to the tissue bath. In seven centres, ryanodine was added as a bolus directly into a relatively large volume tissue bath while in four centres a smaller volume tissue bath was used which was perfused continuously with Krebs solution and ryanodine. Figure 1 is a diagrammatic representation of the four end-points evaluated in this study. The end-points differ in whether or not they refer to early or late contracture development and to the initial reference tension. All end-points were measurements of time and were expressed in minutes. Measures of early contracture development are time from addition of ryanodine to the first increase in baseline tension (Ot) and time from addition of ryanodine until baseline tension exceeds pre-drug tension (Otp). Measures of late contracture development are time from addition of ryanodine to the development of a contracture of 10 mN above the minimum tension (10t) and time from addition of ryanodine to the development of a contracture of 10 mN above the pre-drug tension (10tp).

DETERMINATION OF OPTIMAL CUT-OFF VALUES

Results from ryanodine contracture tests of 290 individuals diagnosed as MHS (n = 101) or MHN (n = 189) in the three diagnostic centres that pioneered ryanodine contracture testing were used. Values for each end-point were used as predictor variables in four separate logistic regression analyses, with MH status as the outcome variable. MH diagnostic status from halothane and caffeine tests was used as the "true" MH status. The optimal cut-off value for each end-point was defined as the value that best segregated ryanodine contracture test results of MHS and MHN patients. This is the value that would give 50% probability of MH susceptibility if entered in the appropriate logistic regression equation. Values for each end-point that define the 95% confidence interval for likelihood of MH susceptibility were also calculated. The proportion of cases in which there was agreement between the standard diagnosis and the ryanodine contracture test end-points is presented.

In order to attempt to optimize the discriminatory ability of the ryanodine contracture test, the two sets of early and late contracture end-points were used to produce further logistic regression models using a backward stepwise selection approach. Thus in one

Table 1 Cut-off values, based on the probability of normality as determined by separate logistic regression models for each of four proposed end-points of the ryanodine contracture test. The optimal cut-off values for each test for distinguishing between MH susceptible and normal individuals was the time predicting a probability of normality of 50%. A ryanodine contracture test result of a time shorter than this optimal cut-off value indicates that the patient is more likely MH susceptible than not, and vice versa

	Time to end-point (min)			
Probability of normality (%)	Ot	10t	Otp	10tp
5	6	17	6	17
50	13	28	16	30
95	19	39	27	41
>99	23	47	33	50

Table 2 Level of agreement of diagnosis of malignant hyperthermia (MH) by the ryanodine contracture test (RCT) by comparison with MH normal (MHN), MH susceptible (MHS) and overall diagnoses obtained using halothane and caffeine contracture tests carried out according to the European MH Group protocol

Criterion for diagnosis of normal by RCT	% Diagnoses correctly predicted		
	MHN	MHS	overall
Ot >13 min	88.12	93.65	91.72
10t >28 min	84.16	94.65	90.97
Otp >16 min	87.13	94.18	91.72
10tp >30 min	82.18	95.14	90.56

of these models the Ot and 10t end-points were used as predictor variables and in the other model the Otp and 10tp end-points were used. For each of these two models an additional predictor variable describing the interaction between early and late contracture end-points was included in order to assess if the relationship between the time to early and time to late contracture development was of any additional value.

ASSESSING CONSISTENCY OF RESULTS IN FURTHER DIAGNOSTIC CENTRES

In these analyses, the ryanodine contracture test results from another 514 individuals were used. Among this group were included patients categorized as MHEc (abnormal result to caffeine only) and MHEh (abnormal result to halothane only) in addition to MHS and MHN individuals. The ryanodine contracture responses of all MHS and MHN patients for each end-point were used for between-centre comparisons using one-way ANOVA with subsequent Scheffé tests. Individual results of the additional patients for each end-point of the ryanodine contracture test were plotted against MH diagnostic status.

Statistical analyses were performed using the SPSS for Windows v6.0 computer package.

Results

The optimal cut-off values determined from the logistic regression analyses and the 95% confidence interval for the likelihood of MH susceptibility for each end-point of the ryanodine contracture test are shown in table 1. Using the optimal cut-off values, the proportion of patients classified as susceptible or not susceptible to MH by the different end-points was in agreement with standard diagnostic tests in more than 90% of individuals in each case (table 2).

When early and late contracture end-point values and their interactions were used as predictor variables in the generation of the logistic regression models, the final model excluded the interaction variable in each case. Table 3 shows the coefficients and their standard errors and significance values that can be used in the logit expression, z, to determine the probability of individual patients being susceptible to MH. In the model using end-points relating contracture development to lowest baseline tension (Ot and 10t), the logistic regression model predicted correctly MH status in 95.83% of patients (a significant improvement on the model derived using only Ot, $P < 0.05$). When the end-point values were derived from contracture relative to pre-drug tension (Otp and 10tp), the ryanodine contracture test model predicted the status correctly in 92.31% of patients.

Comparison of responses of all MHS and MHN patients from the different centres is summarized in figure 2. It is apparent that there were significant differences between mean values for each of the four end-points for several of the centres. From these results certain consistent trends can be observed. For example, early contracture development was delayed in both MHS and MHN muscles tested in centre 1 compared with several other centres, whereas late contracture development was not. Conversely, differences were observed between centre No. 11 and other centres for both early and late contracture variables. Despite these differences, mean values for

Table 3 Details of the coefficients (B), the standard errors of the coefficients (SE) and their significance values (α) generated by the two logistic regression models that used early and late contracture variables as predictor variables. The probability that an individual does not have malignant hyperthermia can be calculated from the results of the ryanodine contracture test using the logistic probability expression,

$$p = \frac{1}{1+e^{-z}},$$

where $z = B_0 + B_1$ (early contracture time) $+ B_2$ (late contracture time)

Contracture variables used in model	Variable								
	Constant			Early contracture variable			Late contracture variable		
	B_0	SE	α	B_1	SE	α	B_2	SE	α
Early variable = Ot Late variable = 10t	−8.25	1.26	<0.01	0.263	0.059	<0.01	0.168	0.059	<0.01
Early variable = Otp Late variable = 10tp	−7.07	0.98	<0.01	0.154	0.038	<0.01	0.148	0.032	<0.01

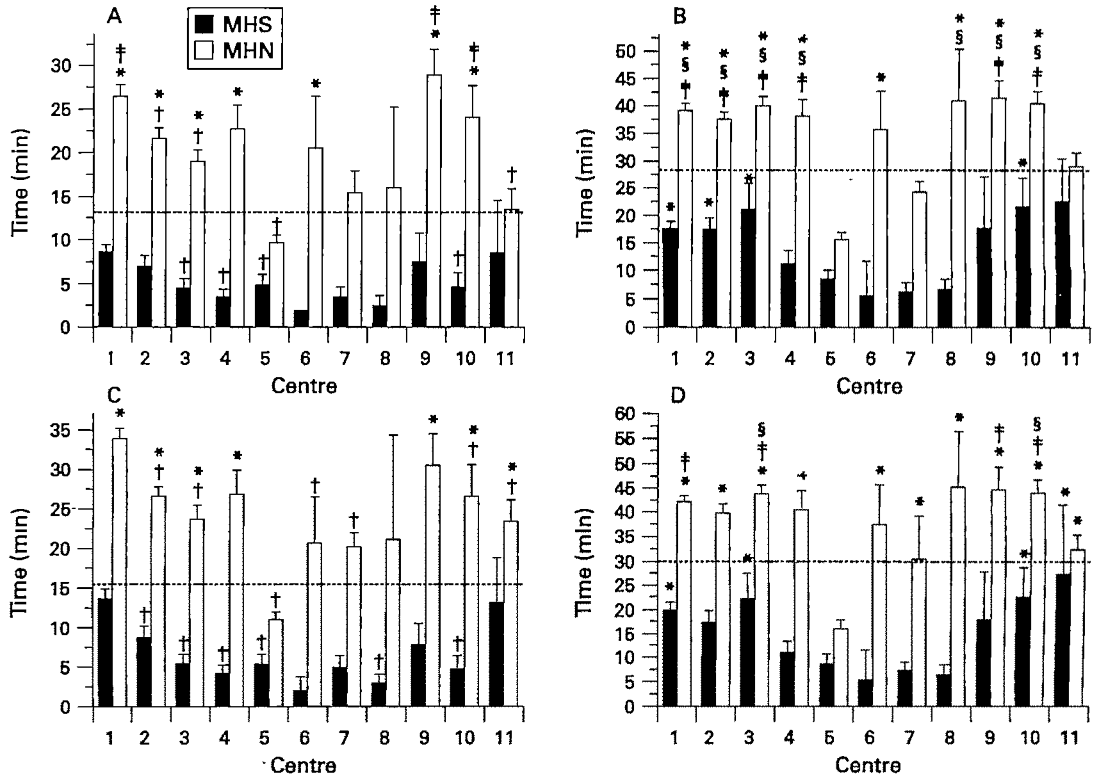

Figure 2 Mean (95% confidence intervals) times for ryanodine contracture responses for four different end-points according to each diagnostic testing centre. The end-points evaluated were: (A) time from addition of ryanodine to the first increase in baseline tension (Ot); (B) time from addition of ryanodine to development of a contracture of 10 mN above the minimum tension (10t); (C) time from addition of ryanodine for baseline tension to return to pre-drug tension (Otp); and (D) time from addition of ryanodine to development of a contracture of 10 mN above pre-drug tension (10tp). MHN = Malignant hyperthermia negative; MHS= malignant hyperthermia susceptible. MHS and MHN results were compared between centres using one-way ANOVA and Scheffé tests, with $P \leq 0.05$ as statistically significant: *compared with centre No. 5, †compared with centre No. 1; ‡compared with centre No. 11; §compared with centre No. 7. The horizontal dotted lines represent the cut-off points above which logistic regression analyses of the results of a subset of 290 patients predicted a greater than 50% likelihood of the patient not having malignant hyperthermia; the upper and lower horizontal dashed lines represent the corresponding 95% and 5% cut-off points respectively.

MHN and MHS muscle responses in each centre were separated by the 50% probability cut-off points derived from logistic regression analysis for each end-point with two exceptions. The 28-min threshold did not separate the mean values for the 10t end-point for MHS and MHN muscles tested by centre No. 7. Of greater concern was that mean values for both MHN and MHS muscles tested by centre No. 5 were below the threshold time for all end-points.

As the results from centre No. 5 were consistently and markedly different from those of the other groups, the results from centre No. 5 were not included in figure 3 in which the results of 446 ryanodine contracture tests studies (excluding patients used in the generation of the models) were compared with the MH diagnostic categories of the patients. It was our intention to conduct further analyses to study the general applicability of the logistic regression models in discriminating between MHS and MHN, but in light of the differences found between the results of different centres, this was felt to be inappropriate.

Discussion

The main aim of this study was to assess the between-centre variation in results obtained using a standardized protocol for ryanodine contracture testing in the diagnosis of malignant hyperthermia. In order to evaluate variability it was necessary initially to determine cut-off values for the different end-points that have been proposed by individual groups on the basis of their own pilot studies.[10 11] The protocol for ryanodine contracture testing used in this study has been adopted by the European MH group after agreement between the MH units in Leeds, Würzburg and Hamburg which pioneered ryanodine contracture testing in MH in Europe. The concentration of ryanodine used (1 μmol litre^{-1}) was agreed as the best compromise between attempts to improve discrimination between MHS and MHN muscles and the practical consideration of how long each test took to conduct. Using this protocol we have shown that it is possible to discriminate between MHS and MHN individuals, as diagnosed by standard *in vitro* contracture testing with caffeine and halothane, in more than 90% of patients. Better discrimination is achieved by combining results of early and late contracture development, although no significant difference between the two approaches in determining the end-point values was detected in this study.

The logistic regression analysis used in this study not only enabled objective determination of cut-off values for the different end-points but it also provided a means of improving the discriminatory power of the ryanodine contracture test and a means of estimating the likelihood of MH susceptibility from a given ryanodine contracture test. The validity of such estimations does, however, assume that results obtained by laboratories other than those used in the generation of the logistic regression equations are from the same population. We found significant differences

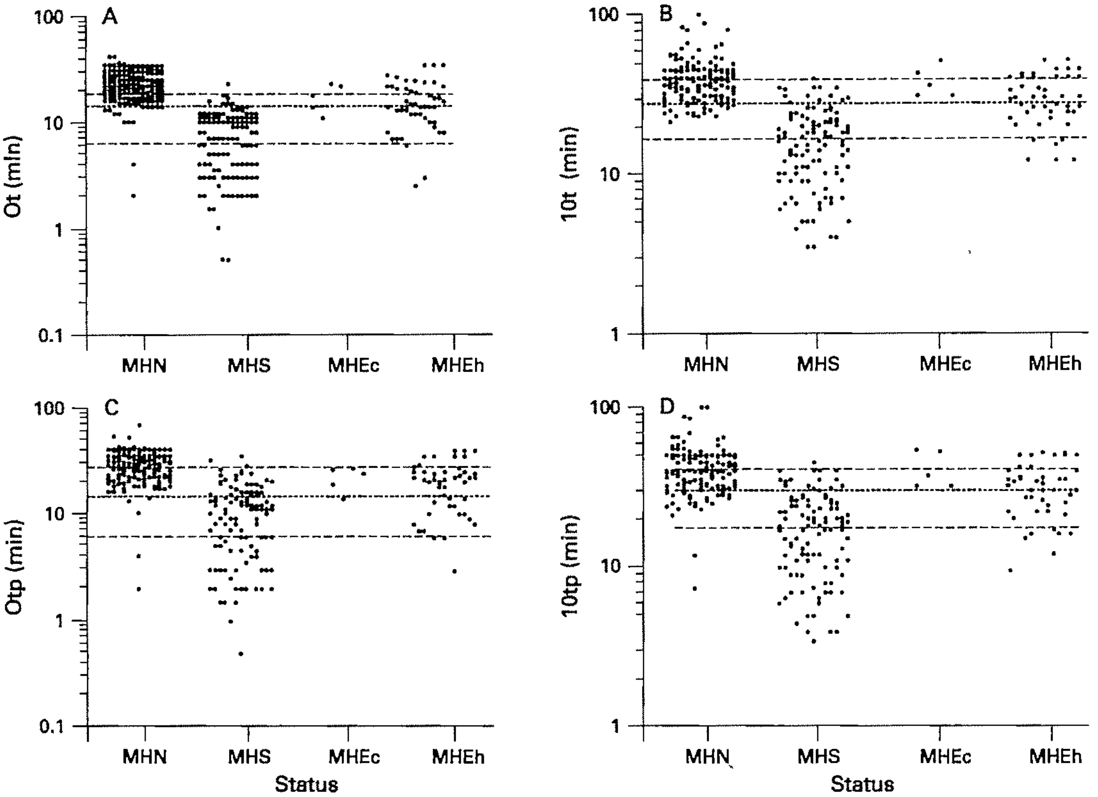

Figure 3 Distribution of ryanodine contracture test results for the four different end-points compared with diagnostic status indicated by conventional contracture testing for 446 patients. The end-points evaluated were: (A) time from addition of ryanodine to the first increase in baseline tension (Ot); (B) time from addition of ryanodine to development of a contracture of 10 mN above the minimum tension (10t); (C) time from addition of ryanodine for baseline tension to return to pre-drug tension (Otp); and (D) time from addition of ryanodine to development of a contracture of 10 mN above pre-drug tension (10tp). MHN = Malignant hyperthermia negative; MHS = malignant hyperthermia susceptible; MHEc = malignant hyperthermia equivocal, abnormal response to caffeine only; MHEh = malignant hyperthermia equivocal, abnormal response to halothane only. Data points may represent more than one patient. The horizontal dotted lines represent the cut-off points above which logistic regression analyses of the results of a different set of 290 patients predicted a greater than 50% likelihood of the patient not having malignant hyperthermia: the upper and lower horizontal broken lines represent the corresponding 95% and 5% cut-off points, respectively.

in ryanodine responses between several centres, and in some cases these were large enough to compromise the use of common variables for discriminating between "normal" and "abnormal" ryanodine contracture responses. The degree of variability in ryanodine contracture results between the different laboratories suggests that it would be inappropriate to define common cut-off values until the reasons for the variability are clarified.

The reason for the disparity between the results of the different centres is not yet apparent. There are some methodological differences in the way ryanodine contracture testing was conducted in the different laboratories. For example, in eight centres, a separate dedicated tissue bath was used for ryanodine contracture tests, while in three it was not; in seven centres ryanodine was added as a bolus directly into a relatively large volume tissue bath while in four centres a smaller volume tissue bath was used which was perfused continuously with Krebs solution and ryanodine. Also, in six centres the ryanodine contracture test was performed simultaneously with the halothane and caffeine tests while in the other five centres it was not. While it would be ideal for all centres to use exactly the same methodology, these differences do not correlate with the differences found in ryanodine contracture test results.

However, there is an analogous situation with the diagnostic halothane and caffeine tests. In these tests, common threshold concentrations of halothane and caffeine are used successfully by all centres, but the size of contracture developed at threshold concentrations varied between centres (European MH Group, unpublished data). It is possible that such differences may be a result of inherent population differences. It is now known for example, that the prevalence of different mutations associated with MH susceptibility varies between countries and regions.[15] As with the ryanodine contracture test, however, these findings are perhaps more suggestive of inadequate standardization of the contracture testing protocols. That such inter-laboratory variation has apparently not been a problem with the halothane and caffeine tests is perhaps a reflection of the robust nature of the current diagnostic criteria, but it may also explain partly the necessity for the equivocal group defined by these criteria.

We have compared the ryanodine contracture test with results obtained using standard halothane and caffeine diagnostic tests. With this approach it is not possible to say if the overlap obtained between MHS and MHN groups was caused by less than perfect discriminant ability of the ryanodine contracture test or if it was the standard diagnostic tests that were wrong. When considering the ability of the ryanodine contracture test to determine the true MH status of patients characterized as MHE by halothane and caffeine tests alone, it can be seen from figure 3 that this is possible in a proportion of MHE patients. The proportion of MHE patients it is possible to re-classify depends on the degree of certainty, or confidence, that is required of the MH diagnosis. This in turn is a reflection of the use of the diagnostic procedure. For example, for clinical use a very high degree of confidence is required before labelling an individual as MH normal as the consequences of a false negative diagnosis are potentially most serious. On the other hand a lesser degree of confidence is required for the ryanodine contracture test to confirm an MHE individual as being likely to be truly susceptible to MH. The logistic regression model approach can be used as a refinement for phenotypic characterization of MH family members for use in genetic linkage studies.[14] In this case the addition of a ryanodine contracture test could be used to estimate the probability of a particular phenotype when other tests produce indeterminate results.

It was not our intention to assess if ryanodine contracture tests could possibly replace the caffeine or halothane tests, or even both, in MH diagnostics. In order to do that it would be necessary to conduct all three types of test on a large series of individuals who, from the details of their clinical reaction, could be deduced to be almost certainly truly susceptible to MH (e.g. by the method of Larach and colleagues[16]) and also another series of individuals who are at low risk for the condition.[17] Initial results from such investigations, albeit with relatively small numbers of patients, are promising in that no overlap between ryanodine contracture responses in low and high risk groups has been found.[10 11] In common with previous work, we conclude that the ryanodine contracture test protocol used in this study can usefully discriminate between MH susceptible and normal individuals but the degree of variability between results from different centres cautions against the use of common diagnostic cut-off values. Greater standardization of techniques used by the European MH Group laboratories in the performance of *in vitro* contracture tests is required and, until this is achieved, each laboratory should be encouraged to define its own cut-off values for the ryanodine contracture test.

CITATION CLASSIC

Commentary

Johnstone M. The human cardiovascular response to Fluothane anaesthesia. *British Journal of Anaesthesia* 1956; **28**: 392–410.

It would be difficult to overstate the significance for anaesthetic practice of the synthesis of halothane in 1951 by Suckling and its first use in clinical anaesthesia by Johnstone in 1956. This event probably represented the biggest pharmacological advance in anaesthesia since the introduction of neuromuscular blocking agents into anaesthesia in 1942 by Griffith and Johnson. Before 1956, the most commonly used volatile anaesthetic agent was ether. With its relatively high therapeutic ratio, it could be given safely by the less experienced using uncalibrated vaporizers but the lower therapeutic ratio of halothane demanded further technological advances in anaesthesia, including the development of calibrated anaesthetic vaporizers. Its administration via low flow circle systems necessitated the development of readily available and inexpensive volatile gas monitors, and the use of this non-explosive anaesthetic agent also permitted the huge expansion in electronic monitoring devices which occurred in the two decades subsequent to its introduction.

This article by Johnstone represents a fine example of the high quality clinical observations made by his contemporaries and the early eminent pioneers of anaesthesia. Although embroidered by a vast number of subsequent clinical investigations and research, many of his observations remain as pertinent today as they did in 1956. For example, he observed that halothane induced dose-dependent hypotension in association with bradycardia. He ascribed this to depression of the sympathetic nervous system with sparing of the parasympathetic nervous system; consequently, many of these changes could be antagonized by administration of atropine. He also noted that cardiac arrhythmias occurred during halothane anaesthesia, although they were uncommon, possibly because of routine premedication with atropine. Ventricular arrhythmias occurred more commonly in the presence of hypercapnia and many responded to increased alveolar ventilation, although Johnstone did not appreciate that the mechanism was a reduction in Pa_{CO_2}.

Many other aspects of this article serve to remind us of the considerable advances which have taken place in anaesthesia in the past three decades. Interpretation of the supposedly beneficial effects of cutaneous vasodilatation awaited the ability to monitor arterial $P\text{co}_2$ rapidly and easily; the importance of flow as opposed to pressure is not evident in this article. Subsequently, modern assessment of the cardiovascular system with measurement of cardiac output, filling pressures in the heart and direct arterial pressure has revealed that halothane has no effect on peripheral vascular resistance and that hypotension is produced largely by direct myocardial depression. But these changes may be attenuated to some extent during spontaneous respiration as a result of the hypercapnia induced by the powerful respiratory depressant effects of halothane.[1]

Johnstone exhibits little appreciation of the effect of IPPV on venous return and the reliance on a pure α adrenergic agonist, methoxamine, to maintain arterial pressure would now be regarded as illogical.

Other non-cardiovascular observations made by Johnstone have stood the test of time, for example the low incidence of nausea and vomiting, absence of stimulation of secretions, and smooth induction and recovery from anaesthesia. Tachypnoea induced by all volatile agents is diminished by administration of opioids and this was noted by Johnstone: only the peculiar description of diuresis after halothane anaesthesia was unfounded.

Today, the use of halothane is declining rapidly in advanced Western countries because of concern regarding its hepatotoxicity.[2] The fact that the number of deaths induced by halothane per annum in the UK has always remained small in relation to the deaths caused by paracetamol poisoning, bears witness to the inherent safety of halothane anaesthesia. However, the continued availability of paracetamol "over the counter" but restriction in use of halothane reflect the demands put upon anaesthetists to strive for perfection and total safety; this is preventing the continued use of the drug because of medico–legal fears in the event that jaundice follows halothane anaesthesia. None the less, halothane is still used widely in many countries and the drug is used frequently in experimental investigations of the cellular effects of anaesthetics.

This article of Johnstone's may therefore have no more relevance today than to serve as an example of the value of good clinical observations. However, it marks a milestone in the development of anaesthesia, not only with regard to a major clinical pharmacological advance, but also the subsequent development of anaesthetic gas delivery and monitoring systems and the start of a period of rapid growth in our physiological and pharmacological understanding of anaesthesia.

THE HUMAN CARDIOVASCULAR RESPONSE TO FLUOTHANE* ANAESTHESIA

BY

MICHAEL JOHNSTONE
Department of Anaesthetics, Royal Infirmary, Manchester

TRIFLUOROETHYL vinyl ether (Fluoromar) was the first fluorinated volatile compound to be used in clinical anaesthesia (Krantz, et al., 1953; Orth and Dornette, 1955). Its lower limit of inflammability was 3 per cent of the vapour. Prior to this a series of fluorinated compounds was investigated by Robbins (1946) who observed that the anaesthetic potency of a fluorinated compound was greatly increased by the insertion of a second halogen atom. This work has been extended by Raventós and Suckling (1956) and the compound CF_3-CHClBr (2 : bromo 2 chloro 1 : 1 : 1 : trifluoro ethane) was found to have excellent anaesthetic properties in animals as well as being nonexplosive and noninflammable when mixed in high concentrations with oxygen. This compound will be referred to as Fluothane.

Fluothane is a colourless liquid with a specific gravity of 1.86 at 20° C. and its boiling point is 50.2° C. at 760 mm Hg pressure. Its vapour pressure is 439 mm Hg at 20° C. Vapour concentrations within the anaesthetic range have a pleasant and nonirritant odour. The compound is decomposed by light but is stable if stored in amber-coloured bottles; the action of light is prevented by thymol 0.01 per cent w/w. Decomposition does not take place in the presence of warm soda lime.

The pharmacology of Fluothane has been investigated in detail by Raventós (1956). It is about four times as potent as di-ethyl ether with a therapeutic ratio about twice that of ether. Surgical anaesthesia can be rapidly induced in animals with from 2 per cent to 4 per cent of the vapour in oxygen and maintained for several hours on 1 per cent with excellent relaxation and spontaneous respiration. Recovery of consciousness is rapid—two to ten minutes—even after prolonged anaesthesia. Salivary and mucous secretions were abolished in nonatropinized animals and neither retching nor vomiting occurred during induction, maintenance, or recovery from anaesthesia. Cardiac irregularities did not appear during any phase of anaesthesia though ventricular tachycardia and ventricular fibrillation were precipitated by the intravenous injection of adrenaline and noradrenaline to dogs anaesthetized with the drug.

A consistent finding in most animals was a fall in blood pressure which was directly proportional to the concentration of Fluothane vapour inhaled. This effect has been related to a block of the sympathetic ganglia with splanchnic vasodilation. The hypotensive effect was minimal with the 1 per cent vapour concentration used for maintenance.

Histopathological studies revealed minor cytological changes in the livers and kidneys of experimental animals after prolonged Fluothane anaesthesia. These changes did not appear to be associated with significant functional or biochemical alterations.

In view of the rather attractive pharmacological properties of this drug a clinical trial was begun. This paper is a report on the effect of Fluothane on some 500 patients. The list of operations performed on them is given later. Some of the patients would come under the heading of "good risks", whilst others could be described as "grave risks" and a still greater number would fall into intermediate categories. This initial report will be concerned mainly with the cardiovascular effects of Fluothane when administered from a Boyle's apparatus.

METHOD

The smaller (Trilene) bottle of a Boyle's apparatus was found to provide a vapour concentration of from 0.2 to 4.2 per cent at 25° C. with a gas flow of 10 litres a minute, Fluothane filled to the 100ml mark, and the plunger fully withdrawn. Under similar circumstances with 50 ml of Fluothane in the bottle the vapour range was 0.1 to 2.8 per cent. With the plunger fixed at 3 mm above the surface of the liquid the vapour range was 0.6 to 4.8 per cent.

It is obvious that only approximate values of vapour concentrations can be obtained when using this equipment for prolonged anaesthesia. In recording the strength of Fluothane vapour used in the clinical trial I will refer to a mark on the extended scale (fig. 1B) which was fixed alongside the control lever of the bottle and gives the approximate vapour concentration as calculated from a chart provided for this particular vaporizer. In all cases the 10-litre gas flow remained constant and consisted of 5 litres of oxygen and 5 litres of nitrous oxide; the plunger was always fully withdrawn; and the liquid maintained approximately at the 50 ml mark.

Blood pressures were estimated by sphygmomanometry and radial pulse palpation in all cases before induction and at frequent intervals thereafter. Respiratory rates were recorded at frequent intervals. Continuous electrocardiography was used

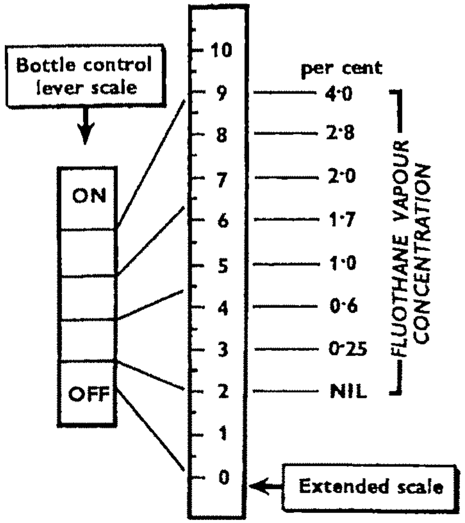

FIG. 1A

Diagram of the extended scale showing the vapour concentrations available at 25°C with 100 ml of Fluothane in the bottle, the plunger fully withdrawn, and a gas flow of 10 litres a minute.

during most major operations; cardiograms were obtained of disturbances of rhythm which occurred before or during the administration of the anaesthetic.

Premedication.

Atropine only, 0.6 mg thirty minutes before induction .. .. 108 cases
Atropine 0.6 mg with pethidine 50 mg before induction .... 392 cases

Induction of Anaesthesia.

In all cases, except where otherwise stated, anaesthesia was induced with a sleep dose of thiopentone (250 mg) injected intravenously followed by 50 mg of suxamethonium and oropharyngeal or orotracheal intubation. The induction of anaesthesia with Fluothane will be made the subject of a separate study and report.

Series One Vapour concentration 2.2 to 3.2 per cent approximately; lever mark 7 to 8; plunger fully withdrawn; 50 ml of Fluothane in the bottle.

This initial series consisted of fifty adults with normal cardiovascular and respiratory systems undergoing operations such as herniorrhaphy, mastectomy, thyroidectomy (nontoxic), varicose vein, and various orthopaedic procedures. Each operation lasted a minimum of twenty-five minutes and took place with the patient in the supine position. Each patient was premedicated with atropine 0.6 mg and pethidine 50 mg and an airway inserted under the thiopentone-suxamethonium sequence. Respiration was then controlled with oxygen, nitrous oxide and Fluothane (mark 7 or 8) until the return of spontaneous respiration a few minutes later. Anaesthesia was then maintained with a similar mixture till the end of the operation.

Smooth anaesthesia persisted throughout the period of operation in all cases, without narcotic or relaxant supplementation. Adequate relaxation was always present. The respiratory rate tended to increase during Fluothane anaesthesia and particularly with surgical stimulation, the average rate during the operations being 28 respirations a minute. The transition from suxamethonium apnoea to spontaneous respiration under Fluothane anaesthesia was made without coughing or straining In each case reflex activity returned within two or three minutes of stopping the anaesthetic and was followed by a five- to ten-minute period of apparently natural sleep from which the patient resented being roused. Full consciousness then returned and was not associated with any restlessness, retching, or vomiting; none of the patients complained of nausea.

The administration of Fluothane vapour in this concentration range caused a rapid fall in blood pressure within two or three minutes of starting. In 35 cases the systolic pressure dropped to between 60 and 80 mm Hg and the hypotension was associated with brisk vasodilatation with an increase in the volume of the peripheral pulse; the skin became warm, dry, and pink, and remained in this state throughout the period of anaesthesia. There was no capillary oozing from the cut tissues though the larger vessels bled normally.

As the blood pressure fell during Fluothane anaesthesia the pulse rate invariably became slower and rates as low as 45 beats a minute were observed. Atrioventricular nodal rhythms were seen in five patients, atrioventricular dissociation with interference in two, and an unusual form of sinus arrhythmia with coupling of sinus beats was seen in two patients (fig. 2B). In all these cases sinus rhythm was restored by the intravenous administration of atropine 0.5 mg. This dose of atropine also raised the systolic pressure from 60 to 80 mm Hg in three patients.

In most cases the hypotensive effect persisted throughout the period of anaesthesia. In eight cases the systolic pressures, after initial falls to 80 mm Hg, rose gradually to 100 mm Hg and persisted at this level for the remainder of the operations.

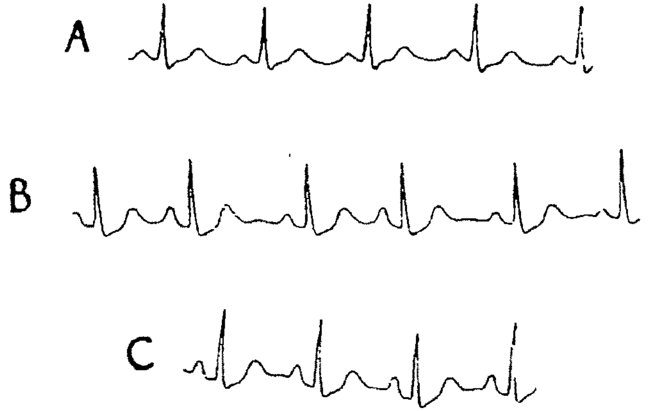

FIG 2

A Before induction

B. After thirty minutes Fluothane (scale mark 8) anaesthesia, note the unusual coupling of the sinus beats.

C Thirty seconds later, after atropine 0 5 mg intravenously

In nine patients the hypotension outlived the narcosis by twenty minutes. There were no increases in pulse rates during the recovery periods, and in several patients the rates tended to decrease as the blood pressures returned to normal.

Series Two. Vapour concentration 0.75 to 1.25 per cent approximately; lever mark 6 to 7; plunger fully withdrawn; 50 ml of Fluothane in the bottle.

Fifty patients, with normal cardiovascular and respiratory systems, undergoing operations similar to those in the previous series. Each patient was premedicated with atropine 0.6 mg and pethidine 50 mg administered intramuscularly thirty minutes before induction. An additional dose of 0.5 mg of atropine was mixed with the sleep dose of thiopentone, suxamethonium 50 mg injected and an airway inserted. Anaesthesia was then maintained with oxygen, nitrous oxide 50 per cent, and Fluothane (1 per cent approximately). This concentration provided smooth and even anaesthesia with adequate spontaneous respiration and sufficient relaxation for all the operations. The respiratory rates increased to an average of 30 a minute; this rate could be reduced to any required level by the intravenous administration of pethidine in doses up to 40 mg. The recovery phases were similar in all respects to those in the previous series, except that one patient vomited a few times and two complained of nausea. The patient who vomited stated that she became nauseated shortly after the pethidine was administered pre-operatively and she vomited twice before the induction of anaesthesia. During cold weather it was noted that several patients shivered for a few minutes after recovering consciousness; the shivering required no specific treatment.

The incidence of hypotension was considerably less in this series. The systolic pressures fell to 70 mm Hg in six patients and in the remainder the average systolic pressure during the maintenance of anaesthesia was 100 mm Hg. The mild hypotension associated with Fluothane (1 per cent approx.) anaesthesia persisted throughout the period of anaesthesia in most cases, but in sixteen patients the systolic pressures gradually returned to within normal limits after thirty minutes anaesthesia. A perfectly regular sinus rhythm persisted throughout anaesthesia in all cases, the average rate being 84 beats a minute. Heart rates in general tended to decrease slightly as the operation progressed, and there were no reactionary tachycardias in any patients during recovery from anaesthesia. Throughout the period of anaesthesia in each case the skin remained warm, dry, and pink, with prominent superficial veins. The cardiograms showed no significant changes in the ST segments or T waves.

PRELIMINARY CONCLUSIONS

The results obtained in this series indicated that Fluothane provided very smooth and easily reversible anaesthesia with adequate relaxation for the operations selected. Although relaxation was of a high degree there was no obvious evidence of respiratory depression with the vapour concentrations used. The effects on the cardiovascular system—hypotension and bradycardia—were consistent with a depression of sympathetic activity with sparing of the cardiac parasympathetic mechanism—a syndrome very similar to that induced by high spinal analgesia. Other signs suggestive of depression of autonomic activity were the persistent vasodilatation, the complete absence of sweating, the complete suppression of salivary, bronchial, and gastric secretions, and the absence of vomiting and retching in the recovery period.

It is obvious that the intensity of the cardiovascular reaction to Fluothane anaesthesia is directly related to the vapour concentration used, being minimal with the 1 per cent which appears to be the concentration needed for maintenance in most cases. Many of the patients felt quite hungry and were able to enjoy substantial meals within two or three hours of the operations. There were no obvious signs of postoperative damage to kidneys, livers, or lungs, though the effects of Fluothane on the functions of these organs will be the subject of more detailed investigations.

In view of the encouraging results obtained in the preliminary studies, the use of Fluothane was immediately extended to cover most types of surgical operations on patients with either normal or abnormal cardiovascular and respiratory systems. The only patients excluded were those with obviously diminished blood volumes pre-operatively. An additional 400 cases have now been completed, their ages ranging from 7 months to 86 years. Premedication was either atropine 0.6 mg alone or combined with pethidine 50 mg; anaesthesia was induced with a sleep dose of thiopentone (unless otherwise stated) and an airway inserted under suxamethonium paralysis. The additional 0.5 mg of atropine was usually injected with the thiopentone and omitted only when tachycardia was present or when hypotension was considered to be necessary to limit bleeding, e.g. neurosurgery, mastectomy, etc. Fluothane was used in the vapour concentration range of 0.75 to 1.25 per cent (scale marks 6 to 7) with nitrous oxide and oxygen 50 per cent. Details of the operations for which Fluothane was the main anaesthetic used are as follows:

ABDOMINAL SURGERY	139	cases
Cholecystectomy	28	
Cholecyst-duodenostomy	7	
Gastrectomy, partial	23	
Gastro-enterostomy, with vagotomy	15	
Hemicolectomy	12	
Splenectomy	6	
Adrenalectomy, bilateral	4	
Colostomy	12	
Appendicectomy	27	
Resection of rectum, abdoperineal	5	
GENITO-URINARY SURGERY	129	cases
Prostatectomy, suprapubic	46	
Prostatectomy, per urethral	24	
Cystoscopy, with diathermy, etc.	37	
Nephrectomy	11	
Nephrolithotomy	8	
Nephrostomy	1	
Diverticulum of bladder	1	
Cystectomy, total	1	
ORTHOPAEDIC SURGERY	31	cases
Compression screws, neck of femur	2	
Trauma	3	
Fractures, reduction and fixation	10	
Amputations	16	
HERNIORRHAPHY	23	cases
NEUROSURGERY	29	cases
Craniotomy	15	
Laminectomy	6	
Radiography	5	
Carotid ligation	3	
MASTECTOMY (radical)	17	cases
THYROIDECTOMY	23	cases
Toxic	16	
Nontoxic	7	
GYNAECOLOGY	4	cases
Caesarean section	1	
Colporrhaphy	3	
CHEST SURGERY	5	cases
Mitral valvotomy	3	
Cardiac neurectomy	2	

Fluothane provided excellent relaxation for all these cases with the exception of the laparotomies, some of which required supplementation with relaxants. Adequate spontaneous respiration was present throughout the operations and seldom required any assistance. In the majority of patients the administration of Fluothane caused an increase in the respiratory rate, the depth remaining either unaltered or slightly increased. Surgical stimulation, particularly in the region of the anus, often caused an increase in the respiratory rate, and rates up to 60 a minute have been encountered during haemorrhoidectomy. These rapid rates were not associated with any increase in the resistance of the lungs to inflation nor was there any increase in the tone of the abdominal musculature such as occurs during trichlorethylene tachypnoea. Tachypnoea not associated with anal stimulation can be controlled with pethidine in doses up to 40 mg; that associated with anal stimulation is effectively abolished by suxamethonium.

Brisk reflex activity returned in two or three minutes after stopping the Fluothane in all cases and vomiting during recovery was present in about 4 per cent of patients, being most evident after cholecystectomy. Transient postoperative nausea was present in 8 per cent of the patients.

Fluothane in the concentration range of 0.75 to 1.25 per cent caused a moderate drop in blood pressure in most cases and a drop to 90 mm Hg in 10 per cent of cases. After twenty or thirty minutes anaesthesia the systolic pressure gradually returned to within normal limits in about half of these patients. Anaesthetized patients were often sensitive to changes in posture, and the reversed Trendelenburg position sometimes precipitated a profound hypotension. Sudden loss of blood during anaesthesia was associated with a sudden fall in the systolic pressure without much change in the pulse rate; the reaction to the transfusion of blood or saline was rapid. Traction on abdominal viscera or retraction of brain tissue caused sudden drops of blood pressure with slowing of the pulse rate in about 20 per cent of the patients subjected to these manœuvres.

Essential hypertension, which was present in eighteen patients, caused no significant alterations in the cardiovascular reactions to Fluothane.

The hypotension associated with Fluothane anaesthesia can be prevented or immediately abolished by the intravenous injection of methoxamine hydrochloride (Cummings and Hays, 1956) in 5-mg doses. This drug has invariably produced the desired effect and is much more consistent in its vasopressor action than other drugs of this type. It has not caused any cardiac arrhythmias or tachycardias when administered to patients anaesthetized with Fluothane. The dose should be carefully restricted, as excessive amounts—10 mg and over—may cause severe hypertension. Methoxamine completely prevents the hypotension associated with the head-up position.

Cardiac Rhythm during Fluothane Anaesthesia.

Sinus rhythm has persisted at a steady rate throughout anaesthesia in most cases. Atrioventricular nodal rhythm was extremely rare, probably as the result of the additional atropine administered with the thiopentone during the induction of anaesthesia. The sinus rate has seldom shown any tendency to increase even after periods of anaesthesia up to 270 minutes nor has there been any increase during and after the recovery of consciousness. Ventricular extrasystoles were observed in twelve cases and were either of the isolated variety or coupled with sinus beats (bigeminy); in each case the arrhythmia was associated with impairment of ventilation either as the result of positioning—steep Trendelenburg or lateral positions—or by respiratory depression from relaxants, and in each case was quickly abolished by assisting the respiration.

The operations of thyroidectomy for thyrotoxicosis and bilateral adrenalectomy for carcinomatosis have not been associated with any disturbance of cardiac rhythm during Fluothane anaesthesia. The application of the electric cautery to haemorrhoids and to bleeding points in the prostatic bed has precipitated transient sinus tachycardia with isolated ventricular extrasystoles in four patients, the cardiovascular disturbance being associated with brisk tachypnoea. The reactions have not been observed during Fluothane anaesthesia when the nerve supply to the region has been blocked by a "saddle-block" spinal analgesic.

The shock syndrome—sinus tachycardia, hypotension, vasoconstriction, sweating, and delayed recovery of consciousness—has not been seen in any patient either during anaesthesia with Fluothane or after the recovery of consciousness. Delayed circulatory collapse—24 to 48 hours postoperatively—occurred in three patients after major surgery and is suspected to be related to hypokalaemia.

Relaxants and Fluothane.

The use of relaxants to facilitate the exploration of the peritoneal cavity is probably advisable when using Fluothane anaesthesia. Attempts to produce with Fluothane in all cases the complete paralysis of the abdominal musculature nowadays expected by the surgeons may result in unnecessarily severe degrees of hypotension requiring postural adjustments.

In the initial stage of this part of the investigation 15 mg of d-tubocurarine were injected intravenously into each of ten patients anaesthetized with Fluothane (scale mark 7); laparotomy for appendicitis was being performed on each and the d-tubocurarine was injected as the peritoneum was being incised. Following the injection of d-tubocurarine in each case there was an immediate drop in blood pressure to between 60 and 70 mm Hg. without significant change in the pulse rate.

Controlled respiration was then necessary in three patients, and in one of these the peripheral pulse disappeared completely during positive pressure inflation of the lungs, and a cyanotic pallor developed; the slightest pressure on the rebreathing bag obliterated the carotid pulse which returned slowly and sluggishly when the pressure was withdrawn. The appendicectomy was hurriedly completed and neostigmine 2 5 mg with atropine 0.5 mg were administered intravenously. As soon as spontaneous respiration commenced there was a dramatic improvement in the patient's circulation: the systolic pressure rose to 70 mm Hg and the pulse was easily palpable at the wrist. Three minutes later a severe bradycardia with hypotension recurred—neostigmine effect—and was modified by a further 0.5 mg of atropine; consciousness returned in fifteen minutes and the systolic pressure became normal two hours later; subsequent recovery was uneventful. Similar syndromes of somewhat less alarming degrees occurred during controlled respiration in the other patients. All patients seemed to be hypersensitive to the inhibitory effects of neostigmine on the heart and required unusually large doses of atropine to counteract this effect.

For the subsequent twenty adult laparotomies the dose of d-tubocurarine was restricted to 5–10 mg, depending on the size of the patient. This dosage produced satisfactory relaxation with spontaneous respiration which required assisting in a few cases. Two mitral valvotomies were successfully performed with this technique, using only assisted respiration throughout; in both these cases the relaxation provided by the Fluothane (scale mark 6½) was quite adequate, the d-tubocurarine being given to depress a little the spontaneous respiration. Neostigmine was considered necessary for a few cases in this series and severe bradycardia occurred in spite of a reasonable dose of atropine. In view of the consistent hypersensitivity to the cardio-inhibitory effects of neostigmine the further use of d-tubocurarine during Fluothane anaesthesia was abandoned.

Suxamethonium in 50 mg doses intravenously was then administered during Fluothane anaesthesia. It caused no further fall in systolic pressure, in fact the systolic pressure frequently increased by from 10 to 15 mm Hg. Similarly, controlled respiration during suxamethonium apnoea under Fluothane (scale mark 7) did not produce any obvious impairment of the peripheral circulation. Over 200 patients have now received suxamethonium 50 mg intravenously under Fluothane anaesthesia without any adverse effects on their cardiovascular systems. In the management of abdominal cases a small dose of suxamethonium (30 to 50 mg) is given intravenously as the peritoneum is incised so as to permit the easy exploration and exposure of the pathological viscus. Subsequent doses are seldom required until the closure of the peritoneum when the suxamethonium is repeated, the Fluothane providing adequate relaxation and spontaneous respiration for the major part of the operation.

Heart Disease and Fluothane Anaesthesia.

Seventeen patients with clinical and electrocardiographic evidence of myocardial disease secondary to coronary insufficiency—eight of them had angina of effort and six had previous histories of congestive heart failure—have been anaesthetized with Fluothane (scale mark 6¼) for periods up to two hours. The operations included prostatectomies, cholecystectomies, and hemicolectomies. Throughout the periods of anaesthesia there was no significant evidence of further myocardial damage and all the patients recovered uneventfully. One of these patients had a severe anginal attack on arrival at the operating theatre and the details of the case are as follows:

Case 1. Male, 48 years. Muscular and well nourished. For transthoracic cardiac neurectomy for the relief of intractable angina of effort. The electrocardiogram showed inverted T waves in the six V leads, with erect T waves in the classical limb leads. No cyanosis, oedema, or arteriosclerosis Lungs normal. Blood pressure 120/85. Premedicated with atropine 0.6 mg and pethidine 50 mg. A few minutes after arrival at the theatre the patient complained of severe precordial pain and dyspnoea. His pulse rate was 115 beats a minute and his blood pressure 120/80, and the electrocardiogram showed depression of the ST segment on lead 2 (fig 3A) Anaesthesia was immediately induced with thiopentone 200 mg intravenously (without additional atropine) followed by suxamethonium 50 mg and orotracheal intubation; this caused no change in the electrocardiogram Anaesthesia was then maintained with oxygen, nitrous oxide 50 per cent, and Fluothane (scale mark 7). Smooth spontaneous respiration returned in three minutes by which time the pulse rate had dropped to 88 beats a minute and was of much better volume, the systolic pressure had fallen to 70 mm Hg; the skin became warm, dry, and pink, and the ST segment returned to its normal isoelectric position (fig. 3D). Fifteen minutes later, just prior to the opening of the pleural cavity, 7.5 mg of d-tubocurarine were administered intravenously and respiration gently assisted to prevent the complete collapse of the left lung For the next twenty minutes anaesthesia was maintained with Fluothane (scale mark 6¼), the systolic pressure persisted at 70 mm Hg, the pulse rate gradually slowing to a steady 65 beats a minute, and the skin remaining warm and dry. Fluothane was then discontinued and within five minutes, although the pulse rate and blood pressure were gradually rising, the skin became clammy and cool. Fluothane (scale mark 6¼) was started again and in a few minutes the skin became warm and dry, the blood pressure stabilized at 70 mm Hg systolic and the pulse rate at 65 beats a minute. The operation was successfully completed after 80 minutes anaesthesia. Methoxamine hydrochloride 5 0 mg was injected intravenously at the end of the operation. Fifteen minutes later the patient was awake and rational with a blood pressure of 130 mm Hg systolic and a pulse rate of 88 beats a minute. Recovery was uneventful.

Eleven patients with electrocardiographic evidence of hypertensive heart disease have been anaesthetized with Fluothane for periods up to 2¼ hours without the development of any significant evidence of further myocardial damage. In these patients the systolic pressure did not fall below 100 mm Hg. The following case history illustrates one

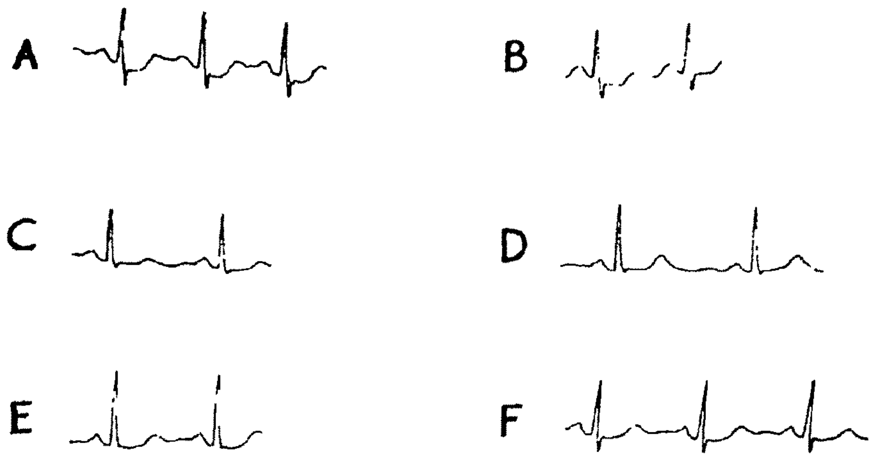

Fig. 3

of the more severe hypertensives during Fluothane anaesthesia:

Case 2 Female 66 years Craniotomy and removal of a right frontal glioma. Frail and thin Fully conscious Blood pressure 210/120 with electrocardiographic evidence of hypertensive heart disease (fig 4A) No cyanosis or oedema, lungs normal Premedication atropine 0 6 mg with pethidine 50 mg Induced with thiopentone (without additional atropine) followed by suxamethonium 50 mg and orotracheal intubation A severe derangement of cardiac function followed the injection of thiopentone (fig 4B) and was abolished immediately (fig. 4C) by the rapid insufflation of Fluothane vapour (2 per cent approx in oxygen). the patient was adequately oxygenated at the time of the appearance of this arrhythmia. Anaesthesia was then maintained for 2¼ hours with oxygen nitrous oxide 50 per cent, and Fluothane (scale mark 6). During the period of anaesthesia the systolic blood pressure did not drop below 130 mm Hg and bleeding from the operation area was negligible Blood replacement therapy was not necessary and the patient responded to instructions within fifteen minutes of the conclusion of the operation Recovery was uneventful

Effects of Fluothane on Cardiac Arrhythmias present before Induction.

Auricular fibrillation was present in eight patients before induction. The fibrillation was associated with coronary sclerosis in two patients, mitral stenosis in one patient, pulmonary emphysema in three, and thyrotoxicosis in two patients. Throughout the operations the auricular fibrillation was unchanged and the ventricular response decreased in each case. All patients made uneventful recoveries.

Frequent ventricular extrasystoles were observed in seven patients before operation. In six of these the ectopic beats disappeared completely during Fluothane anaesthesia but returned with the return of consciousness; one of these cases is illustrated in figure 5. The incidence of ectopic beats in the seventh case remained unchanged during the induction, maintenance, and recovery from anaesthesia.

Pulmonary Disease and Fluothane Anaesthesia.

Twenty-eight patients with chronic hypertrophic pulmonary emphysema have

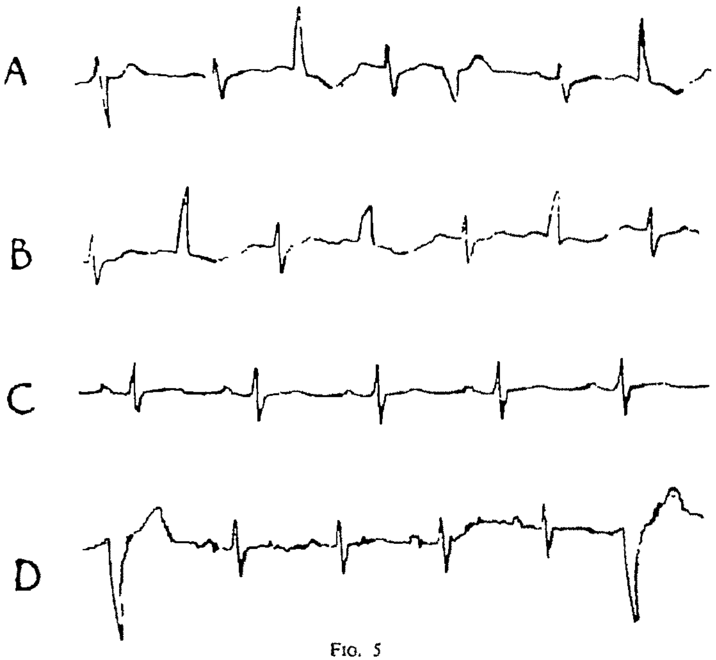

Fig. 5

Female, 75 years For removal of a rectal polyp. Irregular pulse No oedema or cyanosis Blood pressure 140/90 Premedicated with atropine 0 6 mg with pethidine 50 mg All Lead 2

A Before induction
B After thiopentone 200 mg intravenously
C After five minutes Fluothane anaesthesia
D During recovery of consciousness

been anaesthetized with Fluothane. In one case the pulmonary disease was secondary to severe kyphoscoliosis, the remainder being due to chronic bronchitis. Three of these patients had severe cor pulmonale syndromes with orthopnoea, cyanosis, and congestive heart failure at intervals. The operations were mainly prostatectomies. Each patient was premedicated with atropine and pethidine and anaesthesia was induced with the usual sleep dose of thiopentone followed by suxamethonium 50 mg and the insertion of an airway; one patient was induced with Fluothane (scale mark 8) in oxygen. In each case the Fluothane anaesthesia was associated with smooth and easy respiration with the disappearance of the bronchiolar constriction associated with the disease; cyanosis disappeared and the patients became pink and well oxygenated; muscular relaxation was excellent and bleeding was minimal. Recovery of consciousness was prompt in all cases and there was no evidence of the shock syndrome. In the more severe cases there appeared to be an improvement in their respiratory functions postoperatively. Clinical details of one of these cases are as follows:

Case 3 Male, 43 years Haematuria and pyuria due to prostatic calculi Severe kyphoscoliosis with cor pulmonale Cyanosed, orthopnoeic, and confined to bed for the past six months; occasional oedema of the dependent parts Blood pressure 130/90: Sinus rhythm, 125 beats a minute, with severe right ventricular strain

First anaesthetic Cystoscopy Induced with thiopentone 250 mg intravenously followed by suxamethonium 50 mg and the insertion of an airway Apnoea persisted for the next thirty minutes during which time the patient was ventilated with nitrous oxide in oxygen 30 per cent, during this period the pulse was rapid and feeble, the systolic blood pressure 70 mm Hg and sometimes much lower A cyanotic pallor persisted throughout the period of anaesthesia and was associated with clammy sweating Weak spontaneous respiration returned after thirty minutes and consciousness returned twenty-five minutes later. The patient was very distressed and dyspnoeic for several hours afterwards.

Second anaesthetic. Three months later, Fluothane now available. For suprapubic prostatectomy Patient's cardiopulmonary condition unchanged Patient arrived at the theatre in a severely orthopnoeic state, cyanosed and sweating, pulse rate 125 a minute, blood pressure 135/90, electrocardiograph showed sinus tachycardia with right ventricular strain (fig. 6A) Anaesthesia was induced with Fluothane (scale mark 8). After two minutes the patient was obviously unconscious but not adequately relaxed for easy intubation; 50 mg of suxamethonium were immediately injected intravenously and an orotracheal tube inserted without difficulty and without electrocardiographic disturbance. During the period of suxamethonium apnoea the patient's lungs were very difficult to inflate but this difficulty disappeared with the return of spontaneous respiration three minutes later For the next 90 minutes anaesthesia was maintained smoothly with Fluothane (scale mark 7). During this time respiration was spontaneous and offered no resistance to inflation. The systolic blood pressure was maintained at 70 mm Hg, with a regular sinus rhythm at 110 beats a minute (fig 6B). Relaxation was excellent and bleeding was minimal—the operation was performed with the patient in the Trendelenburg position 30 degrees. Throughout the operation the patient's skin remained warm, dry, and pink Consciousness returned within fifteen minutes of stopping the anaesthetic and recovery was uneventful. After the operation the patient stated that his breathing felt easier than it had done for several months.

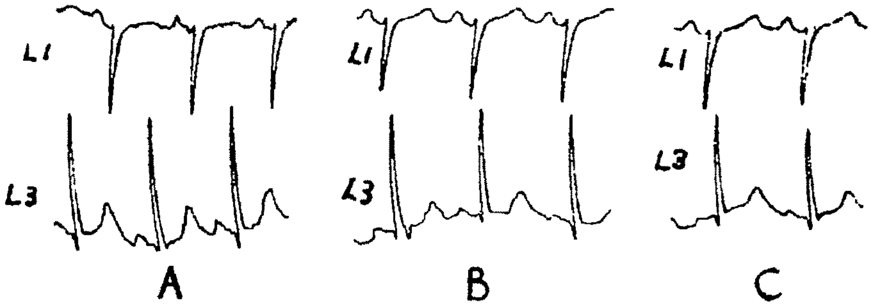

Fig 6

Case 3. See text for details Leads 1 and 3

A. Before induction
B. After Fluothane anaesthesia for forty minutes.
C. During the recovery of consciousness

In addition to the emphysematous patients there were three patients with suppurative bronchiectasis and three with active pulmonary tuberculosis. There were no operative or postoperative pulmonary complications in any of these patients. During anaesthesia with Fluothane there was a complete absence of salivary, mucous, and bronchial secretions in these patients.

Jaundice and Fluothane Anaesthesia.

Eight adult patients with jaundice have been anaesthesized with Fluothane for periods up to two hours. In seven patients the jaundice was due to carcinoma of the head of the pancreas and cholecystduodenostomy was done in each case; two of these patients had hypertensive heart disease, one with auricular fibrillation and intraventricular block. The eighth patient became jaundiced after an attack of acute cholecystitis. Each patient was premedicated with atropine 0.6 mg with pethidine 50 mg and anaesthesia was induced with the usual dose of thiopentone—with additional atropine—followed by suxamethonium 50 mg and orotracheal intubation. Anaesthesia was then maintained with Fluothane (scale mark 7). Maintenance of anaesthesia was smooth and uneventful in all cases, without any clinical or electrocardiographic evidence of further cardiovascular damage; recovery of consciousness was as quick as in the nonjaundiced cases. Seven patients made uneventful recoveries, the jaundice gradually disappearing in two or three weeks; one patient, with carcinomatous deposits in the liver, died on the seventh postoperative day from the effects of biliary peritonitis.

Uraemia and Fluothane Anaesthesia.

Fluothane (scale mark 6 to 7) was administered to ten patients with uraemia secondary to urinary obstruction due either to prostatic hypertrophy or to ureteric obstruction by pelvic neoplasm. In addition, twelve elderly males were admitted with uraemia secondary to prostatism; normal blood urea levels were restored in each of these cases by preoperative catheter drainage. Details of the patients who were still uraemic at the time of operation are as follows:

Case 4 Female, 48 years. Anuria of at least 48 hours duration, secondary to obstruction of both ureters by pelvic neoplasm. Blood urea 380 mg per cent; serum potassium 6.54 mEq ; blood pressure 170/100 mm Hg Patient drowsy and dehydrated, radial arteries difficult to palpate, suggesting vasospasm of considerable degree, no visible or palpable veins on arms or legs Premedicated with atropine 0.6 mg and pethidine 50 mg

Anaesthesia was induced with Fluothane (scale mark 8) and an orotracheal tube inserted without difficulty and without electrocardiographic changes after two minutes (fig. 7B). Anaesthesia then maintained for the next 45 minutes with Fluothane (scale mark 6½), during which time a left nephrostomy was performed without difficulty, relaxation being excellent, bleeding minimal, and spontaneous respiration remaining efficient

Immediately after the induction of anaesthesia the systolic blood pressure dropped to 70 mm Hg and brisk vasodilatation occurred with the appearance of several large veins on the forearms which permitted the easy intravenous administration of fluids and glucose to combat the potassium intoxication The electrocardiogram, which pre-operatively showed evidence of potassium intoxication (fig 6A) remained completely unchanged throughout the operation

Consciousness returned five minutes after the cessation of Fluothane inhalations and the blood pressure returned to 170 mm Hg systolic a few minutes later. There was no postoperative nausea or vomiting Immediately after the operation there was a steady flow of urine from the nephrostomy and three days later the blood potassium was subnormal (fig 7), this was rectified by the oral administration of potassium The blood urea, after a gradual rise to 440mg per cent on the third day after the operation, had returned to normal by the 21st postoperative day

Case 5. Female, 51 years Anuria for two days as the result of ureteric obstruction by pelvic neoplasm. Fully conscious, condition good, blood urea 120 mg per cent, serum potassium normal Induced and maintained with Fluothane for thirty minutes during which time urinary flow was re-established by the insertion of ureteric catheters Blood chemistry gradually eturned to normal in seven days

Case 6 Female, 53 years Clinical details essentially similar to Case 5. After twenty minutes of Fluothane anaesthesia, a pre-operative blood urea of 153 mg per cent had returned to normal a week later

Case 7 Male, 75 years. Acute retention of urine due to prostatic hypertrophy Completely disorientated and confused, blood urea 135 mg per cent. Heart and lungs normal Anaesthesia induced with thiopentone 250 mg (with additional atropine) and maintained by Fluothane (scale mark 7) for 65 minutes whilst a suprapubic prostatectomy was successfully performed. Consciousness returned fifteen minutes after the end of the operation and there was no evidence of shock. Twenty-four hours later the patient was quite rational and the blood urea returned to normal seven days later.

Case 8. Male, 83 years, with prostatic hypertrophy. Blood urea 243 mg per cent on admission and reduced to 87 mg per cent after four weeks catheter drainage A suprapubic prostatectomy was successfully performed under Fluothane anaesthesia lasting 55 minutes Postoperatively there was a progressive rise of the blood urea level to 350 mg per cent on the 15th day, this was associated with a diuresis and normal blood electrolytes most of the time Seven days later the blood urea had returned to 83 mg per cent and the patient had become ambulant and active.

Case 9. Male, 68 years. with prostatic hypertrophy. Blood urea on admission was 123 mg per cent and reduced to 74 mg per cent by seven days catheter drainage Suprapubic prostatectomy then performed under Fluothane anaesthesia. Postoperatively the blood urea rose to 112 mg per cent on the third day and was within normal limits by the tenth day

Case 10. Male, 79 years. Clinical details essentially similar to Case 9.

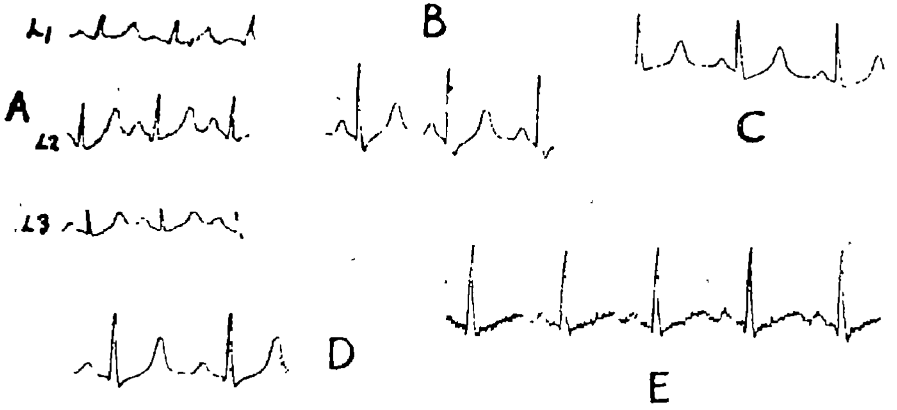

Fig. 7

Case 4 See text for clinical details. All. except A, are Lead 2.

A Before induction. Leads 1, 2, and 3. Serum potassium 6 54 mEq
B After induction and intubation under Fluothane anaesthesia
C. After forty minutes of Fluothane anaesthesia
D During the recovery of consciousness
E. Three days later Serum potassium 3.08 mEq.

Case 11. Male, 67 years Clinical details essentially similar to Case 9.

Case 12 Male, 63 years Clinical details essentially similar to Case 9

Case 13 Male, 68 years Clinical details essentially similar to Case 9

Deaths following Surgery under Fluothane Anaesthesia.

No deaths have occurred under Fluothane anaesthesia. Six patients have died in the postoperative period and the details are as follows:

(1) Female. 47 years Bilateral adrenalectomy for generalized carcinomatosis due to malignant disease of the breast Pathological fractures of the ribs. pleural effusions, and multiple secondaries in the liver. Emaciated and anaemic The bilateral approach to the adrenals was used and the patient tolerated the operation very well Blood pressure remained within normal limits throughout and consciousness returned five minutes after the completion of the operation Twenty-four hours later the blood pressure began to fall and the patient died twenty hours later in spite of the intensive use of vasopressors of various kinds.

(2) Male. 61 years Died seven days after a suprapubic prostatectomy. Autopsy revealed bilateral suppurative pyelonephritis and old standing suppurative bronchiectasis Cause of death was toxaemia due to sepsis

(3) Male, 68 years. Amentia secondary to cerebral atrophy as the result of cerebral arteriosclerosis Bedridden and incapable for several months Scattered moist sounds at both lung bases Cerebral angiography and pneumoencephalography performed under Fluothane anaesthesia of 65 minutes duration. Consciousness and full reflexes returned within fifteen minutes without any evidence of shock or collapse. Prior to recovery of consciousness a considerable amount of purulent sputum was aspirated from the bronchi The patient died 48 hours later from what appeared to be hypostatic pneumonia. Autopsy revealed a terminal bronchopneumonia

(4) Baby, seven months old For removal of a huge occipital meningoencephalocele Heart and lungs normal. Premedicated with atropine 0 4 mg. Anaesthesia induced with Fluothane (scale mark 8). Intubation of the trachea was impossible because of the extreme degree of neck flexion caused by the tumour A nasopharyngeal tube was inserted and anaesthesia smoothly maintained for the next 2½ hours with Fluothane (scale mark 7) During this time the meningocele was excised along with a large amount of brain tissue Blood loss was moderately severe and was not satisfactorily replaced. The baby commenced to cry and move its limbs within five minutes of stopping the anaesthetic Death occurred twelve hours later and permission for autopsy was not obtained.

B

(5) Male. 73 years Cystoscopy and suprapubi prostatectomy Fit and well nourished Heart and lung normal, blood pressure 170/100. Blood urea 83 m per cent Twenty-six years history of diabetes mellitus having insulin 20 units twice daily with appropriat diet Blood sugar immediately before operation wa 240 mg per cent No urinary evidence of ketosis Premedicated with atropine 0 6 mg and pethidin 50 mg Anaesthesia induced with thiopentone 250 m (with additional atropine 0 4 mg) followed by suxa methonium and the insertion of an airway. Th operation was performed under Fluothane (scal mark 6½) without difficulty in 75 minutes, relaxatio was adequate without relaxants, bleeding was minimal and the systolic blood pressure did not drop belo 110 mm Hg Blood transfusion was not required Recovery from anaesthesia was complete in fiftee minutes

Twelve hours later the patient became restless an the blood sugar rose to 480 mg per cent. The appro priate therapy was instituted, but the response wa unsatisfactory, and the patient died from wha appeared to be peripheral circulatory failure 36 hour later During the first 24 hours postoperatively ther was a satisfactory urinary output Hypokalaemia wa not excluded Autopsy failed to reveal the cause o death

(6) Female, 41 years Craniotomy and partial re moval of a pituitary tumour. Obese Heart and lung normal Premedicated with atropine and pethidine Anaesthesia induced and maintained for 3½ hours wit Fluothane Consciousness returned within fiftee minutes after the end of the operation and the patient condition was excellent for the next twenty-four hours A sudden and unexpected collapse then occurred an the patient died within a few minutes. Autopsy faile to reveal the cause of death.

DISCUSSION

The general picture of the huma cardiovascular system during Fluothan anaesthesia is one of vasodilatation com bined with hypotension and bradycardia The vasodilatation—as evidenced by dry warm, and pink skin with prominen superficial veins—becomes obvious withi a few seconds after the start of inhalation and persists throughout the period o anaesthesia, even when minimal concen trations of vapour are inhaled. It does no appear to be affected by haemorrhage o by surgical stimuli

The hypotensive effect is directly re lated to the inhaled vapour concentration being minimal with the lower concentra tions used for the maintenance of anaesthesia. In just less than half of the patients the hypotensive effect diminished as the anaesthetic continued: whether this is due to an increasing tolerance to the drug or to a diminishing output by the vaporizer cannot be stated but it is obvious that, for a drug of this potency, much more accurately controlled and calibrated vaporizers should be incorporated in the anaesthetic apparatus. Sudden haemorrhage causes an immediate and precipitous fall in systolic pressure, and the response to intravenous transfusion of blood or saline is equally rapid. The hypotensive effect of Fluothane can be safely prevented or abolished by the intravenous administration of methoxamine, if considered necessary. Patients under Fluothane anaesthesia are particularly sensitive to the vasopressor effects of methoxamine and doses in the region of 5 mg are usually adequate.

The use of d-tubocurarine with controlled respiration would appear to be contra-indicated during Fluothane anaesthesia. It would seem that d-tubocurarine, which is known to depress synaptic conduction in the sympathetic ganglia (Langley, 1918; Robbins and Lundy, 1947), in these circumstances causes such a profound degree of sympathetic block that intermittent positive pressure respiration obstructs the flow of blood through the lungs with consequent collapse of the systemic circulation.

Some degree of slowing of the pulse rate has always followed the administration of Fluothane, even to patients premedicated with atropine 1.0 mg. The mechanism of the slowing is not yet fully understood, but it is undoubtedly based on overactivity of the cardiac vagus. Whether this vagal overactivity is due to active stimulation of the parasympathetic nerves to the heart, or to an increase in vagal tone secondary to depression of the normal sympathetic counteraction, remains to be seen. Until further knowledge is obtained it would seem to be advisable to premedicate all patients with atropine in the appropriate dosage.

Light Fluothane anaesthesia has produced only minimal electrocardiographic evidence of increased irritability of the human heart. Twelve patients developed ventricular extrasystoles during the maintenance of light anaesthesia in circumstances in which the elimination of carbon dioxide was obviously impaired. Several other patients were subjected to similar degrees of ventilatory impairment and failed to show any electrocardiographic evidence of arrhythmia. Ventricular tachycardia has not been observed in any patient.

The most striking effect of Fluothane anaesthesia has been the complete absence of the shock syndrome—tachycardia, hypotension, sweating, pallor, and vasoconstriction—during and immediately following surgical operations. This was particularly evident after the more severe operations and especially in patients with advanced cardiovascular and respiratory diseases. Postoperative hypotension persisted for one or two hours in three patients in whom the replacement of blood loss was either inadequate or tardy; nevertheless, their skins remained warm and dry, their pulse rate averaged 90 beats a minute, and the recoveries of consciousness were not retarded.

The apparently complete protection which Fluothane anaesthesia has provided against surgical shock in this investigation may be related to a suppression of sympathetic activity during anaesthesia. Evidence is accumulating which indicates that blockade of the sympathetic division of the autonomic nervous system during surgery prevents the type of circulatory collapse which may lead to death (Martin, 1955; Overton and De Bakey, 1956; Ross and Herczeg, 1956; Hershey et al., 1956). The excellent results obtained with Fluothane anaesthesia in patients with severe pulmonary emphysema and cor pulmonale may also be related to its effects on sympathetic ganglia: Bromage (1956) has recently demonstrated that ganglionic blockade caused significant increases in the vital capacities of patients with pulmonary hypertension.

As the result of recent clinical observations it has been suggested that Fluothane anaesthesia may be followed by a diuresis which may cause hypokalaemia in those patients whose potassium levels are already diminished by disease. Although the evidence is by no means complete, it would be advisable to ensure adequate electrolytic and fluid replacements in those patients who present evidence of electrolytic depletion prior to or after anaesthesia with Fluothane.

One elective Caesarean section was successfully performed under Fluothane (scale mark 7½) anaesthesia. Relaxation was adequate, bleeding minimal, the child was fully conscious when delivered from the uterus, and the uterus retracted normally after the removal of the placenta. Recovery of consciousness was complete in seven minutes after the removal of the face mask and there was no evidence of shock, vomiting, retching, or nausea.

SUMMARY

(1) Fluothane—a new nonexplosive volatile anaesthetic agent—has been administered to 500 patients, including many with cardiovascular, pulmonary, renal, and hepatic diseases complicating the surgical lesions. Each patient was premedicated with atropine, either alone or combined with pethidine, and anaesthesia was induced in most cases with a sleep dose of thiopentone.

(2) Smooth and rapidly reversible anaesthesia has been maintained in all cases by the continuous administration of Fluothane vapour, using a Boyle's vaporizer and a gas flow of ten litres a minute with 50 per cent oxygen and nitrous oxide.

(3) Cardiovascular changes suggestive of depression of sympathetic activity have consistently been observed and which, to a certain extent, were modified by atropine and by the strength of the vapour concentration inhaled. The shock syndrome has been completely absent in all cases.

(4) There has been a complete absence of salivary, mucous, and bronchial secretions in all cases throughout the period of anaesthesia. Nausea, vomiting, and retching during recovery have been absent in over 90 per cent of the patients.

(5) Cardiac arrhythmias of the vagal type were observed when the higher concentrations of Fluothane vapour were inhaled. These arrhythmias included sinus bradycardia, atrioventricular nodal rhythms often with interference, dissociation, and an unusual form of sinus

arrhythmia with coupling of the sinus beats. Atropine restored normal sinus rhythms in these cases. Their incidence has been completely eliminated by adequate atropinization.

(6) Ventricular arrhythmias have been observed only in the presence of inadequate ventilation in lightly anaesthetized subjects and were of a mild degree. Ventricular tachycardia has not been observed.

(7) Cardiovascular collapse—slow pulse and profound hypotension—has followed the combined use of d-tubocurarine and controlled respiration on patients anaesthetized with Fluothane. Such reactions did not occur when suxamethonium and controlled respiration were used in conjunction with Fluothane anaesthesia.

(8) Tachypnoea has occurred during surgical stimulation in patients lightly anaesthetized with Fluothane. The reaction can be controlled by pethidine or by regional nerve block.

(9) No deaths have occurred under anaesthesia. The details of six postoperative deaths have been presented.

(10) It has been suggested that Fluothane anaesthesia may cause an immediate postoperative diuresis which may lead to serious electrolytic depletion in those patients already in a state of electrolytic deficiency as the result of disease.

ACKNOWLEDGMENTS

I should like to express my sincere thanks to Dr Suckling of the General Chemicals Division of Imperial Chemical Industries Ltd, Widnes, for providing supplies of Fluothane. and also to Dr Raventos and Dr Paget of Imperial Chemical (Pharmaceuticals) Ltd., Manchester, for their constant assistance. I am also most grateful to my surgical colleagues at the Royal Infirmary and at Crumpsall Hospital, Manchester, for their co-operation

CORRESPONDENCE

Anaesthesia after exhaustive exercise

Sir,—There are no reports on the effect of preceding exhaustive exercise, such as marathon running, on the course of anaesthesia. We report an extreme case. A healthy 21-yr old (65 kg, 173 cm) active jogger (40–60 km/week) presented for day-case tonsillectomy under general anaesthesia. Three days earlier he had run his first marathon and told the anaesthetist that his legs were painful. He had difficulty in lying down on the operating table. After operation, he told us that after 30 km of the marathon he had become so exhausted that he could remember little of the rest of the race.

An i.v. anaesthetic was used, supplemented with 70% nitrous oxide in oxygen. The drugs given and their total doses were as follows: glycopyrrolate 0.2 mg, propofol 280 mg, fentanyl 300 µg and rocuronium 50 mg. Residual neuromuscular block was antagonized at the end of operation with neostigmine 2.5 mg and glycopyrrolate 0.5 mg. During surgery, 2500 ml of crystalloid i.v. solutions were given. Postoperative analgesia was achieved with ketoprofen.

After operation the patient was able to breathe satisfactorily but despite normal responses to peripheral nerve stimulation he appeared extremely weak, that is he was unable to lift his head or even his hand. Because his condition had not improved after 6 h, he was moved to the local university hospital. Thirteen hours after operation the patient had to be escorted to the toilet by two people. Next morning he was able to walk but still complained of muscle pain, especially in his legs. The muscle pain disappeared gradually over the next 3 days.

Eight hours after operation total blood count, C-reactive protein concentrations, serum concentrations of creatinine, sodium, potassium and chloride, and blood-gas analysis, serum lactate, ammonium ion and insulin concentrations were normal. The only abnormal value was serum creatine kinase (1572 u. litre^{-1}, normal value <285 u. litre^{-1}), which was still high 2 days after operation (5 days after the marathon it was 338 u. litre^{-1}), but was within normal limits by 10 days after operation (114 u. litre^{-1}). The patient underwent ^{31}P-magnetic resonance spectroscopy (MRS) 33 h after the beginning of anaesthesia to assess the status of skeletal muscle energy metabolism.[1, 2] He was re-examined 5 months later for comparison. The patient resumed his usual training schedule 1 month after surgery.

From the MRS studies we found no evidence of altered energy metabolism of striated muscle to anaesthesia after exhaustive exercise. Variables assessing the main energy producing pathways (phosphocreatinine hydrolysis, glycolysis or aerobic oxidative phosphorylation) were similar immediately after the incident compared with 5 months later. In contrast, resting concentrations of phosphodiesters were substantially higher immediately after the incident (4.5 compared with 2.7 mmol litre^{-1}). Phosphodiesters are hypothesized to be indicators of release of membrane molecules in muscle cell damage.[3] But muscle overuse is associated with damage to the muscle contractile elements.[4] This damage to the contractile elements could also be an explanation for our phosphodiester results.

After exhaustive exercise, a general anaesthetic could cause some type of interaction between the exhausted muscles and anaesthetic agents. Importantly, significant rhabdomyolysis may occur if succinylcholine is used.

Pain after laparoscopic cholecystectomy

Sir,—We were interested in the review article by Alexander[1] and wish to make some comments regarding local anaesthesia for pain after laparoscopic cholecystectomy.

First, Alexander[1] pointed out that analgesia tended to be given more readily during studies of pain or analgesics and that nearly all patients had received some form of intraoperative analgesia. We strongly support this view. It is difficult to compare postoperative pain when patients received various amounts of analgesics in the perioperative period. For this reason in our published study[2] no opioid or non-opioid analgesics were used for premedication or during the perioperative period. Patients received only halothane and pancuronium during anaesthesia. For postoperative analgesia, patients received metamizol on request, as was usual in our hospital, by nurses who were blinded to the treatment. Postoperative pain was measured using a VAS score. The VAS score was not used as a threshold for administrating metamizol.

Second, the timing of i.p. local anaesthetic (IPLA) is crucial, as it is for an NSAID. In the studies quoted in the review[1] and in our study,[2] IPLA was used after surgery, but in our study, in addition to that of Pasqualucci and colleagues,[3] IPLA was given before and after surgery. Administration before surgery is important for pre-emptive analgesia. Third, the site of administration is important. The quoted studies reported that IPLA was ineffective when given only into the subdiaphragmatic space. In contrast, IPLA was effective for pain relief when given onto the gallbladder bed[4] or into the subdiaphragmatic space and onto the operative area.[2, 3]

Fourth, the local anaesthetic concentration should be important. The quoted studies reported that IPLA was not effective when a low concentration of IPLA (0.15–0.25% bupivacaine) was given in contrast with those[2–4] in which IPLA was effective for pain relief when given in high concentrations (0.5% bupivacaine).

Finally, Alexander[1] concluded that local anaesthetic techniques appear to be more successful for pelvic laparoscopy than for laparoscopic cholecystectomy. We disagree. When IPLA is given at the correct time, on the right site and at the right concentration, it is also effective for pain relief after laparoscopic cholecystectomy. No side effects from IPLA have been reported. Therefore, we recommend routine administration of 0.5% plain bupivacaine 15 ml[2] or 0.5% bupivacaine 20 ml with epinephrine[3] into the subdiaphragmatic space and on the operative area before and after surgery.

4. Chundriger T, Morris R, Hedges AR, Stamatakis JD. Intraperitoneal bupivacaine for effective pain relief after laparoscopic cholecystectomy. *Annals of the Royal College of Surgeons of England* 1993; **40**: 437–401.

Sir,—Thank you for the opportunity to reply to Mraović and Majerić-Kogler, and to acknowledge a material addition to the evidence. In an adequate double-blind, randomized, controlled study,[1] they demonstrated the lesser need for additional analgesics and lower pain scores in those who had bupivacaine injected between the liver and diaphragm and above the hepato-duodenal ligament. Their study was not reviewed because the article was published at the same time as the review[2] was submitted.

Their method was similar to that described in an earlier article by Pasqualucci and colleagues.[3] This was primarily a study of pre-emptive analgesia and either bupivacaine or saline was sprayed above the liver and on the right subphrenic surface either before or after removal of the gallbladder, or both. Distension of the peritoneum occurred before application of local anaesthetic or saline. In those in whom bupivacaine was used at the end of intra-abdominal surgery, pain scores and ratings were lower than those in the placebo group at the end of surgery and 8 h after operation, but similar to those in the placebo group at 4 h (the time at which pain is most intense).[1, 4] Intraoperative i.v. fentanyl was used in a dose which was stated to be 15 mg kg^{-1}!

Whether or not effective local anaesthesia or systemic analgesia provides pre-emptive analgesia during continuing nociception, as distinct from requirements for effective analgesia at the time of nociception, still appears to be in dispute.

Mraović and Majerić-Kogler disagree only with my statement[2] that "local anaesthetic techniques appear more successful for pelvic laparoscopy than for, say, laparoscopic cholecystectomy". However, as they pointed out in their discussion, "six studies compared intraperitoneal bupivacaine for pain relief after laparoscopic cholecystectomy, four of which suggested that intraperitoneal bupivacaine does not reduce pain and two of which suggested that it does."

Nevertheless, the studies of Chundrigar and colleagues,[5] Mraovic and colleagues[1] and Pasqualucci and colleagues[3] suggest with increasing evidence that to which I merely alluded: that local anaesthetic techniques are more likely to be effective when the local anaesthetic is placed accurately at the site of origin of nociception in effective concentrations, rather than relying on movement or diffusion of local anaesthetic to the target area from a convenient site in the peritoneal cavity, especially when such movement is against gravity in a cavity partly filled with gas.

Ondansetron compared with metoclopramide in the treatment of PONV

Sir,—We wish to comment on the study on postoperative nausea and vomiting (PONV) by Diemunsch and colleagues.[1] This is the largest study to date comparing ondansetron with a commonly used antiemetic in the treatment of established PONV, and showed improved outcome for patients treated with the 5-HT$_3$ antagonist. However, we were struck by the fact that even this drug, the newest and possibly most highly promoted antiemetic in the pharmacopoeia, still failed to control nausea in 56% and vomiting in 41% of patients.

A recent review in the *BMJ* by Tramer and colleagues[2] concluded that there is little information in relation to the effectiveness of intervention in established PONV, and that a 25% success rate is perhaps the best that can be achieved. The study of Diemunsch and colleagues goes someway to addressing this insufficiency in the literature and, in addition, had a greater success rate than Tramer and colleagues felt may be the best possible.

However, we feel that the study poses several questions: (1) Can we identify a group at high risk of PONV, and should we make more of an effort to do so using scoring systems such as that devised by Koivuranta and colleagues?[3] (2) If we can identify these patients, is prophylaxis effective? (3) Are there non-drug interventions that can help, such as reducing the length of the preoperative fast,[4] or the use of pre- or intraoperative i.v. fluids?[5] (4) If this study shows the best that can be achieved with single agent therapy, should future research be conducted on double or even triple agent regimens compared with other active comparators?

In a recent audit of PONV and pain in 198 sequential patients in our day-case unit, two (1%) were admitted to hospital, both as a result of vomiting. This is a small but significant number and brings to our attention the economic consequences of PONV and the distress caused by intractable vomiting and the inconvenience to the patient. It is hard to believe that we have optimized our management of PONV; perhaps more co-ordinated research will provide some answers.

Sir,—Harper and Barker ask the question: (1) Can we identify a group at high risk of postoperative nausea and vomiting (PONV), and should we make an effort to do so using scoring systems such as that devised by Koivuranta and colleagues? Several prognostic factors are known to be associated with an increased risk of nausea and vomiting[1, 2]: female sex, previous history of PONY, use of postoperative opioids and previous history of motion sickness. In our study, we identified the prognostic factors for the absence of emetic episodes after administration of the study drug. Sex appeared to influence the antiemetic response, as 72% of male patients experienced no emetic episodes between 15 min and 24 h after drug administration compared with 48% of female patients.

Other factors influencing the antiemetic response include: history of PONV (55% of patients with a history of PONV experienced at least one emetic episode compared with 47% with no history); postoperative opioid analgesia (55% of patients who received opioid postoperative analgesics experienced at least one emetic episode compared with 45% who did not); and benzodiazepine premedication (54% of patients who received a benzodiazepine premedicant experienced at least one emetic episode compared with 40% who did not). Induction of anaesthesia with propofol had no influence on the antiemetic response, as 49% of patients who received propofol experienced at least one emetic episode compared with 50% of patients who did not.

The logistic regression analysis carried out for the absence of an emetic episode between 15 min and 24 h after drug administration showed that: (a) significant prognostic factors, adjusted for treatment, were sex, history of PONV, benzodiazepine premedication and postoperative opioid analgesia. The odds ratio (with 95% confidence intervals) for the absence of an emetic episode in the ondansetron group compared with the metoclopramide group was 2.12 (1.57–2.87), adjusted for the above mentioned prognostic factors (P=0.0001). (b) The adjusted odds ratio associated with sex indicated that males were 2.76 times more likely to experience no emetic episode than females (P=0.0006). Patients having one of the following prognostic factors experienced more frequent emetic episodes: previous history of PONV (odds ratio=0.70; P=0.0237), benzodiazepine premedication (odds ratio=0.56; P=0.0008), postoperative opioid analgesia (odds ratio=0.64; P=0.0040). No significant effect from treatment of the prognostic factors was found.

(2) If we can identify these patients, is prophylaxis effective? Yes, clinical studies confirmed that ondansetron was effective in both the prophylaxis and treatment of PONV.[3-5] Moreover, there are also other benefits from reducing PONV, such as patient global satisfaction,[6] quality of recovery and prevention of delayed recovery.[7]

(3) Are there non-drug interventions that can help, such as reducing the length of the postoperative fast, or the use of i.v. fluids before or after operation? Apart from drugs which are known to have antiemetic properties, such as lorazepam,[8] hydroxyzine[9] and propofol,[10] others factors could enhance the incidence of PONV, such as postoperative pain[11] or movement.

(4) If this study shows the best that can be achieved with simple agent therapy, should future research be conducted on double or even triple agent regimens compared with other active comparators? The incidence of PONV is approximately 60% in both the prevention and treatment studies. The number of complete responders in our treatment study does not reflect the real benefits to the patient. The non-surrogate criteria (for example, global satisfaction of the patient) reflect other benefits which are not sufficiently taken into account. These results could probably be improved with the additional use of drugs such as corticosteroids,[12] as was demonstrated in clinical studies in chemotherapy.

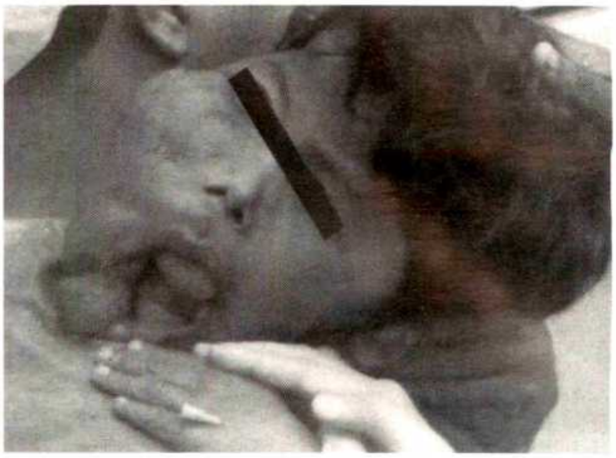

Figure 1 Patient No. 1. A 6-yr-old boy with neurofibromatosis who presented for tracheostomy and debulking of a large intraoral tumour.

Sevoflurane for difficult intubation in children

Sir,—We read with interest the case reports by Mostafa and Atherton[1] in which sevoflurane was used to induce anaesthesia in three adult patients in whom difficult tracheal intubation was anticipated. We wish to report two paediatric patients with a difficult airway where sevoflurane was used as the induction agent.

The first patient was a 6-yr-old boy with neurofibromatosis who presented for tracheostomy and debulking of a large intraoral tumour (fig. 1). He also had a 6 month' history of progressive difficulty in breathing and stridor. Inhalation induction was planned because of airway obstruction. EMLA cream was applied to both hands 1 h before induction. I.v. access was established. Anaesthesia was induced with sevoflurane in oxygen. The concentration of sevoflurane was increased gradually until an end-tidal concentration of 5.5% was achieved. Direct laryngoscopy was performed and revealed a grade III larynx which was grossly deviated to the left. The larynx was intubated uneventfully with a 5.0-mm plain Portex tube orally. Oxygen saturation was maintained at 99% throughout induction.

The second patient was a 11-yr-old girl with a fixed right temporal mandibular joint and a very receded mandible. Her inter-incisor distance was only 1 cm at full mouth opening. Fibreoptic intubation under inhalation induction was planned. I.v. access was established before induction. Anaesthesia was induced with incremental concentrations of sevoflurane in oxygen. A nasal airway was inserted via the left nostril and attached to a T-piece. When the end-tidal sevoflurane concentration reached 5.5%, the trachea was intubated with a 5.5-mm plain Portex tube nasally via the flexible fibreoptic laryngoscope. Both surgery and anaesthesia were uneventful.

A difficult airway in paediatric patients presents a challenge to anaesthetists. Inhalation induction is the technique of choice because it is often difficult to perform awake fibreoptic intubation or tracheostomy under local anaesthesia in children. We agree with Mostafa and Atherton that sevoflurane has many advantages compared with halothane in the management of the difficult airway in both children and adults. The low blood:gas solubility of sevoflurane and consequent rapid induction and rapid recovery are reassuring features in the management of difficult intubation.

Caudal tramadol for postoperative analgesia in hypospadias surgery

Sir,—Prolongation of caudal anaesthesia is indeed a laudable aim. However, I have some concern with the recent article describing the use of tramadol in this role.[1] The evidence that tramadol may be effective in this regard is scanty. There is little evidence that it is safe or effective by the extradural route in adults.

We do not know the incidence of neurological damage that may be caused by this drug, and just one child with a painful or disabling neuropathy would be disastrous. Until evidence emerges of its safety and efficacy in adults, I do not believe that studies of this nature should be carried out in children.

W. Russell

Leicester

1. Prosser DP, Davis A, Booker PD, Murray A. Caudal tramadol for postoperative analgesia in paediatric hypospadias surgery. *British Journal of Anaesthesia* 1997; 79: 293–296.

Sir,—Thank you for the opportunity to respond to Dr Russell about our caudal tramadol study.[1]

Although we agree in principle that studies should not involve children if the relevant data can be obtained from adults, this is rarely possible. In this instance, the significant age-related differences in opioid pharmacokinetics and pharmacodynamics,[2] and vascularity, fat content and volume of the extradural space[3,4] make extrapolation of clinical data from adults to young children rather suspect. Although some initial data may be gleaned from studies of drugs injected into the lumbar extradural space in adults, our results supported the concept that data achieved in this way cannot be used to predict accurately drug pharmacodynamics after caudal injection in children. All but one of 10 adult studies and the one paediatric study published in the past decade that have examined the effects of tramadol after extradural administration have recorded encouraging results. Our findings would not have been anticipated from meta-analysis of these studies. Furthermore, for various well recognized reasons, administration of drugs into the caudal extradural space is much less common in adults than in the very young. If studies examining caudal administration of drugs in adults were required before paediatric studies could proceed, we would often have to rely solely on data from non-randomized, unblinded, uncontrolled studies carried out in developing countries.

The second point about drug safety is a thorny issue but one that is always raised at Paediatric Ethics Committee meetings when a study of a "new" drug is being reviewed. To prove the safety of any drug is almost impossible, but a thorough examination of all published (and any available unpublished) clinical and experimental evidence offers the best possible compromise between ensuring optimal safe care for our patients and advancement of our knowledge base. In this instance we were able to point out that tramadol, which has been widely available in the rest of Europe for more than 20 yr, has an exceptional safety record[5]; to the best of our knowledge no long-term adverse side effects attributable to its use have been reported.

Finally, we did not perform this study because it was possible or because we wished to write another article; we believed that there was a problem (postoperative pain in children undergoing day-case hypospadias surgery) that could be prevented or alleviated. On the basis of previously published clinical work, we hypothesized that the analgesic effect produced by bupivacaine could be usefully prolonged by the addition of tramadol. Similar studies using more conventional opioids have shown that delayed respiratory depression may, occasionally, be a problem.[6,7] Tramadol has the important and significant advantage over other commonly used opioids of having a marked lack of respiratory depressant effects.[8,9] If we had found tramadol to be clinically useful in inpatients, then we would have extended our study to day-case patients. In the light of our initial findings, we did not believe that a study extension was justifiable.

Many of these same arguments were presented and examined carefully by our Paediatric Ethics Committee before commencement of this study. One of the guiding principles used by this Committee in determining whether or not a study should be allowed to proceed is: "Children are not small adults and research should only be done in this group of patients if comparable research on adults cannot answer the same questions". We believe, as did the Ethics Committee, that this principle was strictly adhered to in the conduct of this study.

Bair Hugger active patient warming system

Sir,—I read with interest the case report of Ayala and Coe regarding softening of tracheal tubes when used in conjunction with the Bair Hugger patient warming system.[1] As a result of their case report and subsequent study, they recommended the avoidance of uncut PVC tubes, unless adequately supported, with this warming system.

Having personally experienced a similar problem I have a simple and effective solution. This is to make a small hole in the clear plastic region of the Bair Hugger (designed to cover the patient's head) and to pass the tracheal tube through this, thus effectively removing it from the warmed environment. I have encountered no recurrence of the problem since adopting this method.

Inappropriate use of placebo

Sir,—Fujii, Toyooka and Tanaka compared granisetron with placebo for reduction of postoperative nausea and vomiting (PONV) in middle ear surgery.[1] First, when established treatments are available, research must be compared with existing treatments, not with placebo. I wish to know if granisetron is more or less effective than other antiemetics on offer. Second, the same authors had already proved the effectiveness of granisetron in PONV in gynaecological patients (including a placebo group).[2] Third, by withholding antiemetic therapy in the placebo group until significant morbidity from PONV had occurred represents sub-standard medical care.

2. Fujii Y, Tanaka H, Toyooka H. Optimal anti-emetic doses of granisetron for preventing post operative nausea and vomiting. *Canadian Journal of Anaesthesia* 1994; 41: 794–797.

Sir,—We have already studied the efficacy of granisetron, a selective 5-hydroxytryptamine type-3 receptor antagonist, in preventing postoperative nausea and vomiting (PONV) after gynaecological surgery.[1,2] However, there is no study investigating its efficacy in preventing PONV in patients undergoing middle ear surgery. The incidence of PONV after this surgical procedure is high (62–80%) when no prophylactic antiemetic is given.[3] Therefore, we studied the efficacy of granisetron in the prevention of PONV in this population. Several investigators have previously compared the antiemetic efficacy of such new agents as ondansetron, granisetron, tropisetron and dorasetron with placebo for preventing PONV.[4-7] Similarly, we compared the efficacy of granisetron and placebo for the prevention of PONV after middle ear surgery.

Bradycardia during rapid inhalation induction with sevoflurane in children

Sir,—In common with Sigston and colleagues,[1] we have found inhalation induction with 8% sevoflurane to be rapid and well tolerated in young children. However, the development of profound bradycardia in four children has caused us to reflect on its use. These were healthy children, aged 6 months to 2 yr, undergoing minor surgery. None was premedicated and induction was by inhalation of 8% sevoflurane and 66% nitrous oxide in oxygen, using a standard technique. In all cases the onset of bradycardia occurred during induction with no loss of airway or ventilation. One infant required treatment with atropine because of clinical evidence of a decrease in cardiac output. In the other children heart rate recovered spontaneously when the concentration of sevoflurane was reduced or we changed to using isoflurane.

In the study of Sigston and colleagues, bradycardia occurred in one child who received halothane (age unknown) but not in the sevoflurane group. It is noteworthy that all of their patients received atropine premedication. Baum, Yemmen and Baum reported no arrhythmias when comparing 8% sevoflurane with incremental sevoflurane in unpremedicated children.[2] Johannesson, Floren and Lindahl found an incidence of cardiac arrhythmias of 5% while using incremental sevoflurane in premedicated patients.[3] Otherwise, incremental induction with sevoflurane in children seems to show an increase or have little effect on heart rate.[4]

Those familiar with halothane induction in infants may admonish us for not routinely prescribing atropine where an inhalation induction is planned, if not to dry secretions and thus reduce airway complications, then to offset the myocardial depression which can accompany high concentrations of a volatile agent. The cardiovascular depression produced by sevoflurane is much less than that with halothane, but not absent. The single-handed anaesthetist, anticipating difficult i.v. cannulation, would be well advised to consider atropine premedication when planning inhalation induction with high concentrations of sevoflurane in infants.

Effect of temperature on diaphragmatic function

Sir,—The article by Mills and colleagues described the effect of a 5°C temperature change on the evoked compound potential in the human diaphragm.[1] They found a reduction in the EMG of approximately 60%. This is in agreement with our own findings using electromyography carried out in five children undergoing cardiac surgery under profound hypothermia. We found this effect to be almost completely reversed by edrophonium and concluded it was most likely a result of decreased production or release of acetylcholine (ACh).[2] Further experiments in dogs confirmed this effect.[3] The recent work of England added support for the view that in non-hibernating mammals, cold critically affects ACh production or release.[4]

In the past, much of our information on the effects of hypothermia has come from experiments carried out either in cold blooded animals or on tissues from rats which are genetically closely allied to hibernating animals. These species do not necessarily respond to cold in the same manner as humans and as a result conflicting findings have been reported. This article confirms the critical effect of cold in human neuromuscular conduction. If the effect of hypothermia in humans is caused by a reduction in ACh release, this also has implications for its effect on neuromuscular blocking drugs.[5]

S. Feldman
London

4. England AJ. *Effect of Hypothermia on Neuromuscular Conduction and Blockade*, MD Thesis. London: University of London, 1995.
5. Feldman S *Neuromuscular Block*. Oxford: Butterworth Heinemann, 1996; 128–138.

Sir,—We thank Professor Feldman for his comments on our results. We agree entirely that the most likely mechanism which may explain our observations is indeed impairment of production or release of acetylcholine (ACh). We regret that at the time this did not occur to us and therefore we did not perform the simple edrophonium test. Examination of the human data of Feldman[2] (quoted by Feldman) suggests that the effects of hypothermia on twitch height of arm muscles start at approximately 34.5°C. Interestingly, our data (especially during the transition from warm to cold) suggest that the effects of hypothermia on the diaphragm may be detectable at temperatures even closer to 36°C. One could speculate that there may be differences between the diaphragm and limb muscles in this respect, perhaps because the temperature within limb muscles is often hypothermic in inactive, normal subjects exposed to cold, whereas the diaphragm is not.

BOOK REVIEWS

Review for Intensive Care Medicine. M. W. Sebastian, W. J. Fulkerson and R. L. Reed II (editors). Published by Lippincott–Raven, Philadelphia. Pp. 269.

This book is a collection of more than 700 multiple-choice questions, mainly of the true/false style, designed for candidates sitting the American Critical Care Boards. The style of questions may be unfamiliar and confusing to UK examination candidates. The reader is frequently asked to choose the most/least appropriate answer; on occasion, several of the alternatives offered would appear to be equally acceptable. I found the quality of questions variable and the lack of an index mildly irritating. Questions are based around the chapters in the book's parent text, *Intensive Care Medicine* by J. M. Rippe, and cover most aspects of critical care. The emphasis and spread of topics, not surprisingly, appears to follow the North American practice of intensive care more closely than that of the UK, with a broad scope of system-based questions.

For UK-based trainees sitting the Intensive Care Diploma there is inadequate coverage of respiratory problems; for example the subject of ARDS merits only two questions, as does weaning from mechanical ventilation. Acute renal failure is also covered by two questions, while septic shock is deserving of three. In contrast, psychiatric issues in intensive care are covered more thoroughly, with a total of 53 questions! Subjects not strictly included within the scope of intensive care in the UK, such as coronary care, are well covered, as are haematological problems. Unfortunately, most trainees from an anaesthetic background will find the section on "Procedures and techniques" basic and undemanding; it is unlikely to meet the requirements for the diploma examination.

On a more practical note, the book is soft-backed and presented in American A4 size with more than ample space for note writing. Indeed, for the sake of preserving trainee comfort and scarce natural resources, it may have been better presented in a portable pocket-sized format. The printing of the answers at the end of each chapter was not very reader friendly; I would have preferred to see the book divided into two completely separate question and answer sections.

At present there is a relative paucity of high quality intensive care revision aids. This book will therefore undoubtedly provide a useful addition to the reading material for candidates presenting for the Intensive Care Diploma. But it is unlikely to stand alone as a revision aid and will probably be found lacking in several important areas. As the number of candidates presenting for the Intensive Care Diploma increases, so probably will the availability of high quality, purpose-written revision aids. At such time, I feel this book will be judged to fall far short of the standards required for such a text.

G. Dempsey

Essential Anatomy for Anaesthetists. S. M. Black and W. A. Chambers. Published by Churchill Livingstone, New York. Pp. 198; indexed; illustrated. Price £55.00.

Some teachers who are steeped in obscure educational theories may view the acquisition of a large amount of anatomical knowledge as an unnecessary exercise for undergraduate students of medicine, let alone postgraduate students of anaesthesia. The idea is that learning facts may impede the pursuit of understanding. However, it seems difficult to see how a learner can gain an understanding of anatomy without filing away a lot of Latin names at some point in the process. The authors of this volume state that a sound knowledge of relevant anatomy remains a fundamental requirement for specialists in anaesthesia. The requirements for postgraduate examinations in anaesthesia would endorse this view. In the UK, there is a guaranteed question on anatomy in the primary FRCA examination and a question in the final examination is highly possible.

It seems that the same anatomy text will no longer serve all branches of medicine. We now have speciality-specific texts which include only those areas that are judged to be relevant to the particular specialty. This new book is divided into four chapters, covering the respiratory system, cardiovascular system, nervous system and anatomical regions of special interest to the anaesthetist. These regions of special interest include the thoracic inlet, intercostal spaces, anterior abdominal wall, axilla, antecubital fossa and the orbit. It is slightly strange to have included 18 pages on the skull and the vertebral column in the chapter on the nervous system. Why not a separate chapter? There is nothing on the mandible or the temporomandibular joint, although these are structures of some consequence in some cases of difficult intubation.

The illustrations in this book are exceptionally good. There are very clear black and white line drawings with occasional minimal use of colour—red for arteries, blue for veins and yellow for nerves (although the obturator nerve is shown as a red structure in one diagram). Muscles are coloured brown in some of the illustrations for the larynx and the orbit, but elsewhere muscles are an unobtrusive black and white and in general the illustrations are models of minimalist clarity. There are only two x-rays which are used to illustrate intra-thoracic structures and unfortunately, the key for the lateral chest x-ray is the wrong way round. The lack of other x-rays or scans is perhaps unfortunate as the clinical relevance of the study of anatomy might have been reinforced by, for example the inclusion of magnetic resonance images in the section on the vertebral column and brain, and echocardiography images in the section on the heart.

The book is printed on glossy 11 × 8.5 inch paper, so large illustrations and text can be combined with ease on a single page. The text is easy to read and anatomical names are printed in bold type in the text when the structure is the main focus of the paragraph or section. Blue coloured boxes occur throughout the book and summarize information or provide useful lists (e.g. the somatic innervation of the larynx, branches of the subclavian artery, contents of the antecubital fossa, etc.). All of these are designed to aid learning. Tracheostomy is discussed and illustrated but no other procedure receives such attention and some more clinical correlates might have been useful.

Anatomy will always be an important subject for our specialty and *Essential Anatomy for Anaesthetists* will be a very useful addition to anaesthetic department library shelves. The book is likely to prove popular with candidates for anaesthetic examinations.

While every effort is made by the publishers and editorial committee to see that no inaccurate or misleading data, opinions or statements appear in this Journal, they wish to make it clear that the data and opinions appearing in the articles and advertisements herein are the responsibility of the contributor or advertiser concerned. Accordingly, the publishers and the editorial committee and their respective employees, officers and agents accept no liability whatsoever for the consequences of any such inaccurate or misleading data, opinions or statements. While every effort is made to ensure that drug doses and other quantities are presented accurately, readers are advised that new methods and techniques involving drug usage, and described within this Journal, should only be followed in conjunction with the drug manufacturer's own published literature.
